33.1 INTRODUCTION: DEFINITIONS AND IMPORTANCE

According to the International Trade Centre UNCTAD/GATT, "spices may be defined as one of the various strongly flavored or aromatic substances of vegetable origin obtained from tropical and other plants, commonly used as condiments or employed for other purposes on account of their fragrance and preservative qualities."[3] Condiments are spices alone, or blends of spices that have been formulated with other flavor potentiators to enhance the flavor of foods. The so-called "true spices" (eg, pepper, cinnamon, nutmeg, and cloves) are products of tropical plants, and may be fruit, bark, buds, roots, or other parts. Herbs are usually from leafy parts of soft-stemmed plants of the temperate zone (eg, oregano, marjoram, basil). Spice seeds (eg, mustard, caraway, celery, anise) may be either from tropical or temperate areas. Dehydrated vegetable seasonings (eg, onion or garlic powders) are flavorings with similar uses and problems to those of spices and herbs.

Spices, herbs, and dry vegetable seasonings are chemically and histologically a very heterogeneous group of commodities. Their important properties, processing, and uses are reviewed in several monographs.[49,57,122]

Spices and herbs are important items in international trade. In addition to their household uses, they are used in virtually all categories of the food industry. The markets for spices and herbs in industrialized countries are increasing with the growing popularity of ethnic foods.

33.2 RELATIONS OF SPICES AND HERBS TO MICROBIOLOGICAL QUALITY AND SAFETY OF FOODS

The food microbiologists' interest in spices and herbs is based principally in the facts that they may (1) exhibit antimicrobial activity, (2) occasionally stimulate microbial metabolism, (3) become moldy if held at improper humidity, and (4) often contain large numbers of microorganisms that may cause spoilage or, more rarely, disease, when introduced into food.

33.3 SPICE ESSENTIAL OILS AND OLEORESINS

Spice essential oils are volatile aromatic substances obtained from ground spices by steam distillation, while oleoresins are prepared by extraction of spices using suitable organic solvents or liquid/supercritical CO_2.[33,102] These products offer certain advantages over natural spice powders, ie, freedom from enzymes and microorganisms, uniform dispersion in products, and easy handling and storage. They may be mixed with a carrier (eg, salt) or encapsulated (eg, in starch). However, for certain products they are unable to substitute all functional properties of the original spices, particularly the aroma profile or appearance of the product. For example, in products such as certain sausages in which the spices are visible, particularly pepper and cloves, this is a part of the distinctive quality of the particular meat product. Also the loss of flavor of spice extracts during any cooking process, unless fully enclosed, is greater than that of natural spice. Encapsulated spices retain volatiles better than extracts.[133] The production of a new spice alternative designated "Mildspice-Registered" involves mixing natural spice particles and spice extractives and microencapsulation of this mixture in a dry matrix.[37] Micro-Registered is claimed to combine the true flavor profile of traditionally ground spices with the low microbial counts and convenience of encapsulated variants.

33.4 ANTIMICROBIAL EFFECTS AND ANTIMICROBIAL CONSTITUENTS

There is considerable interest in the use of naturally occurring compounds as alternative food additives to prevent or delay the growth of foodborne microorganisms.[14] Among these materials, the antimicrobial activities of extracts of several spices and herbs have been recognized for many years. Various essential oils and/or their components have been reported as being active against a wide range of bacteria (including spore-formers), and fungi (including yeasts). The major antimicrobials present in some spices and herbs are listed in Table 33-1.

Table 33-1 Major Antimicrobials Present in Some Spices

Antimicrobials	*Spices*	*References*
Allicin	Garlic	138
Allyl isothiocyanate	Mustard	32
Anethol	Anise	51, 140
Capsicidine	Hot paprika	55, 56
Capsaicine	Cayenne, hot paprika	55, 56
Carnosol	Rosemary	21
Carvacrol	Oregano, savory, thyme	11, 80, 84
Cinnamic aldehyde	Cassia, cinnamon bark	51, 116
Cuminaldehyde	Cinnamon, cumin seed	84
Eugenol	Allspice, cloves	17, 51, 96
Geraniol	Ginger, thyme	80
p-menthane compounds	Mint	143
Thymol	Oregano, thyme	11, 84
Ursolic acid	Rosemary	21

The antimicrobial activity of a given spice and extract from it may depend on only one or two of the large number of different chemical compounds that make up the spice oil. Some of the antimicrobial molecules may be common to several spices, whereas others are unique to a few closely related spices. However, the composition and content of essential oils varies from spice to spice and even within the same spice, depending on agricultural practices, geography, and climatic conditions during the growing season. The early literature of the antimicrobial effects of herbs, spices, and their extracts has been reviewed extensively.[36,64,111]

Spices and herbs that contain the most inhibitory essential oils are cloves, thyme, oregano, cinnamon, allspice, cumin, and caraway.[12,69] Onion and garlic juice also contain antimicrobial compounds.[1,53] In cloves and allspice, the major antimicrobial components are eugenol, eugenol acetate, or eugenol methylether; in cinnamon and cassia, they are cinnamic aldehyde, cinnamic acetate, and eugenol; in thyme, they are thymol and carvacrol; in mustard seed, it is allyl isothiocyanate; and in garlic, it is allylsulfonyl allyl sulfide.[9,42,69,71,72,78] The degree of observed microbial inhibition by spices depends on their concentration in media, the method employed to test for antimicrobial activity, and the strains/species of microorganisms.[7,69] There is some evidence that synergistic or cumulative inhibitory effects exist between the components in certain spice extracts.[17,115]

The concentrations of essential oils in spiced food are generally too low to prevent microbial growth.[127,160] Furthermore, levels found to be inhibitory in laboratory media are often insufficient to cause inhibition in foods.[41,69] On the other hand, the antimicrobial potential of essential oils may be enhanced in food in which the contaminants have been stressed.[22,23] In some cases the preservative effect of essential oils may be of practical importance.[17] Cinnamon (about 1%) in raisin bread decreased mold growth and even smaller concentrations prevented production of aflatoxin.[16] In recent studies in Germany, the addition of 11 different spices was tested for controlling mold growth on sliced toast bread. Cloves and oregano in concentrations of 1% to 2% significantly delayed growth of various bread-relevant fungi.[90] Further studies with proper spice mixtures are required to optimize sensory quality and antifungal efficiency for bakery products.

The efficacy of oregano essential oil and to a lesser degree of thyme essential oil as fumigants against fungi (*Aspergillus flavus, A. niger,* and *A. ochraceus* as well as natural microflora of wheat grain) was demonstrated by Paster and coworkers.[115] The minimal inhibitory concentration of oregano oil applied for 24 hours as fumigants was 2.0 μl L^{-1} and it exhibited fungicidal activity at 20 μl L^{-1} level. Because the essential oils tested caused a reduction in the germinability of grains, these materials cannot be used for seed preservation but only to preserve grains destined for consumption.

Addition of 0.5% fresh, finely ground rosemary or 1% rosemary oil to ready-to-eat pork liver sausage before cooking delayed listerial growth during refrigerated storage, however, these levels imparted strong odor and flavor to the product.[114] The antilisterial activity of rosemary appears to be associated with its antioxidant compounds. An antioxidant extract of rosemary (STABEX) obtained by liquid carbon dioxide extraction was an effective antilisterial additive at 0.5% in the same meat product without affecting its characteristics.

The mechanisms of inhibition and destruction of microorganisms by essential oils are varied because their antimicrobial compounds are chemically diverse. It is suggested, because of the similarity in structure of the active components of some essential oils with phenols, that spice oils may affect growth by the same mechanism as phenols. Phenols affect the cell membrane of bacteria by altering permeability and interfering with transport systems, electron transport, and energy production.[71,155]

33.5 STIMULATION OF MICROBIAL ACTIVITIES

It has been observed that some spices accelerated the production of lactic acid and the decrease of pH during production of fermented sausages in which lactic acid bacteria were used as starters.[48,83,161] The stimulatory factor seems to be the manganese content of such spices, a known essential element in the metabolism of lactic acid bacteria.[48,107]

33.6 MICROBIOLOGICAL CONTAMINATION OF SPICES AND HERBS

33.6.1 Sources of Microbial Contamination

Spices and herbs contain those microorganisms indigenous to the soil and plants where they are grown and that survive the drying process. Dust, insects, fecal material from birds and rodents, and possibly the water used in some processes (eg, soaking peppercorns in the production of white pepper), are the main sources of additional contamination.

Microbial counts can vary from one storage period to another depending on moisture content and storage conditions. The viable count is a function of original bioload, proliferation, and die-off. Therefore, the observed counts of samples of the same spice or herb of various lots often show deviations of several logs.[65,69,99,113] The microbiological quality of spices and herbs often reflects the hygienic situation of the region of their production and handling.

33.6.2 Saprophytic Bacteria

The range of microbial contamination as a percentage distribution of aerobic plate counts and mold counts of various spices is charted in Table 33-2. According to this frequency distribution, the highest levels of bacterial contamination was found usually in black pepper, turmeric, the capsicum spices, coriander, and allspice,[10,27,69,85] not infrequently with mesophilic aerobic bacterial counts of $>10^7$ cfu g^{-1}.

In many spices, the aerobic mesophilic spore-forming bacteria originating from soil are dominating in the microflora.[85] Most frequently found species are *Bacillus subtilis, B. licheniformis, B. megaterium, B. pumilus, B. brevis, B. polymyxa,* and *B. cereus.*[10,50,59,74,135] Because during drying and storage many vegetative cells die off, whereas spores survive, aerobic bacterial spores may comprise more than 50% of the mesophilic aerobic plate counts (Table 33-3).[69,106] The proportion of obligately anaerobic spore-formers is usually small.[50,87,94]

Thermophilic anaerobic and aerobic spore-formers are found occasionally.[87] Thus, some spices are potential sources of very heat-resistant spores of bacteria, including thermoduric flat sours, putrefactive anaerobes, and sulfide stinkers. Psychrotrophic bacteria are generally less numerous than mesophiles in spices and herbs.[27]

A wide variety of nonsporing bacteria may also be present in spices. Coliforms are often found[113] but *Escherichia coli* is not frequent (Table 33-4).[10,113,132] Fecal streptococci occur usually in low numbers, rarely reaching the level of 10^4 cfu g^{-1}.[10] Staphylococci and lactic acid bacteria are not frequent in spices.[69]

33.6.3 Pathogenic Bacteria

Spore-forming bacteria (*B. cereus* and *Clostridium perfringens*) that are capable of causing gastroenteritis when ingested in large numbers are frequently found in spices, but usually in small numbers (Table 33-5).[26,27,86,87,113,123,126] However, in extreme cases *B. cereus* counts up to 10^5 cfu g^{-1} were found.[10,85,113,147] *B. subtilis* and *B. licheniformis,* common in many spices,[59] were occasionally responsible for foodborne gastroenteritis.[88,89] Because spores of the above organisms may survive cooking temperatures and may grow at permissive temperatures in many foods, spices harboring these spores must be considered potential health hazards.[120,121]

Although infrequently, salmonellae have been found in a variety of spices.[13,15,113,126,129] Their presence is of special concern when spices are used on foods that are consumed raw or when they are added to foods after cooking.[15] Black and white pepper have both been implicated as causes of salmonellosis due to *Salmonella weltevreden* and *S. oranienburg* infections.[61,137] In 1993, a nationwide outbreak of salmonellosis occurred in Germany because of paprika and paprika-powdered potato chips contaminated by a great number of strains.[92]

Staphylococcus aureus is rarely found in dry spices.[15,120] *Listeria* spp. seem to be even more infrequent in spices and herbs.[85]

Concerning microorganisms of public health concern at low populations in spices, it should be considered, however, that lack of resuscitation, and inhibition by spice components in the lower dilution levels, may yield incorrect results.[113,157]

33.6.4 Fungal Contamination and Mycotoxins

Aspergillus spp., *Penicillium* spp., *Fusarium* spp., *Alternaria* spp., *Rhizopus* spp., and *Mucor* spp. are the most common molds detected in spices, and viable contamination levels of mold are in the 10^3–10^5 propagules g^{-1} range of various samples (Table 33-2).[69,99,113]

A relatively high incidence of toxigenic molds, including *Aspergillus flavus, A. parasiticus, A. fumigatus, A. ochraceus, Penicillium citrinum,* and *P. islandicum* has been detected in some spices.[2,69] Several investigators have found aflatoxins in a range of spices, although the levels were generally low.[54,69,95,99,101,102,125,158] There is no correlation between the severity of microbial contamination and the aflatoxin concentration of spices.[93] Yeasts have been found in spices in low numbers only.[10,97]

33.7 EFFECT OF PRIMARY PROCESSING, PACKAGING, AND STORAGE ON THE MICROFLORA OF SPICES AND HERBS

The various spices require widely diverse harvest and postharvest methods, which affect the microbial content in different ways.[69] The main consideration is to dry the products as rapidly as possible to prevent spoilage while retaining their desirable characteristics. Drying of spices reduces the number of vegetative bacteria present. The remaining flora consists mainly of spore-forming bacteria and

molds, because of their ability to survive long periods on dried materials. The number of viable microorganisms present is a function of packaging and storage conditions. Because of slow oxidation, viable cell counts of dry spices and herbs may decrease during storage. This may partly be the reason why spices and herbs are, in general, apparently more heavily contaminated at import than at retail.[77,132] In a Finnish study, Malmsten et al.[94] found greater viable cell counts in freeze-dried and vacuum-packaged herbs than in those stored in oxygen-containing packages (glass jars) (Table 33-6), and microbial counts were generally higher in samples stored at 23°C than at 35°C. Survival of molds and yeasts inside packages was especially dependent on the presence of oxygen, whereas the dried herbs in different types of packaging contained similar numbers of viable aerobic sporeformers. Of course, the storage conditions that maintain higher viable counts also maintain better color and other sensory qualities.[117,118]

33.8 APPLICATION OF GOOD HYGIENIC PRACTICE AND THE HAZARD ANALYSIS CRITICAL CONTROL POINT CONCEPT

A proposed Draft Code of Hygienic Practice for Spices and Dried Aromatic Plants is under preparation by the Codex Committee on Food Hygiene,[20] describing requirements for environmental hygiene in the production and harvesting area, establishment design, and facilities; personnel hygiene and health requirements; hygienic processing requirements; and end-product specifications. Application of the Hazard Analysis Critical Control Point (HACCP) system in spice production is illustrated in general terms in the example of black pepper by the International Commission on Microbiological Specifications for Foods.[70] Similarly, the American Spices Trade Association published a "Spice Microbiology Hazard Background Review" to lay the groundwork for applying HACCP concepts to the spice trade.[6]

Steps in the production of black pepper (probably the most important commodity of the international spice trade) and typical critical control points (CCPs) are shown in Figure 33-1.[70]

Black pepper is produced from the unripe dried berry of a perennial climbing vine (*Piper nigrum* L.) of far eastern tropics.[49] While the time of harvesting is primarily determined by the maturing of the berry, pepper should not be harvested in wet weather unless mechanical means of drying are available. The moisture content of harvested berries must be reduced to 10% to 15% to minimize microbial growth.

The bulk of the world's pepper production is sun dried. Mechanical drying results in lower microbial contamination. For solar drying the provision of protection from rain, dew, and vermin, and for mechanical drying the cleanliness of the drier and time and temperature of the drying process, are important factors of control. The moisture of the dried berries may be determined. After farm cleaning and preliminary storing of dried peppercorn, pepper is transported to export centers. During storage and transport, it should be protected from insects, high humidity, and rain. Redrying (if necessary), final cleaning, eventually fumigation (for disinfestation), grading, and packing are usually done at exporting centers. At bagging, the moisture content of pepper should be 11% or less. Awaiting and during export, pepper should be stored in moisture-proof bags or at a relative humidity not above 70%. Protection from moisture, prevention of large temperature changes that may create moisture migration and localized moist areas, and freedom from vermin are important control requirements during storing and transport to importing countries. Microbiological decontamination procedures, dealt with in later parts of this chapter, have their specific CCPs appropriate to the specific technologies.

33.9 MICROBIAL SPOILAGE OF SPICES AND FOODS BY MICROORGANISMS FROM SPICES

Because of their low water activities (normally within the range of 0.3–0.65), there is virtually no bacterial spoilage of spices and herbs after drying. However, fungi may grow on them prior to drying and during drying, storing, and shipping, if relative humidity and temperature are permissive, or localized wetting occurs.[74,134] Insect infestation may contribute to the biodeterioration of spices, by carrying mold spores.[136]

Bacterial spore populations in ingredients to be used in low acid products that undergo a mild heat treatment, eg, canned pasteurized luncheon meats, may cause spoilage if mishandling occurs in marketing channels or by consumers. For the canning industry, if an ingredient contributes a heat-resistant microflora in terms of the process being applied, ie, thermophilic spores, then that ingredient becomes the most important determinant of the bacteriological quality of the product, and control over the finished product requires effective control over the spore load of the ingredient.[6,142] Spices can play a major etiological role in mold contamination of certain food products[63,75] and they can cause spoilage if the products provide a proper environment for growth of the molds, and they do not undergo processing that would destroy the fungi. Thus, it is important to determine the types of organisms that could spoil a product and set specifications (microbial or process) for the particular organism or group of organism.[6]

33.10 METHODS OF MICROBIOLOGICAL DECONTAMINATION

In a number of products, the introduction of spoilage organisms or pathogens from spices and herbs must be controlled carefully.[57] In such instances, the use of essential oils and oleoresins or spices that have been treated to reduce the levels of microorganisms is warranted or advisable. Even where there is a low probability of contaminated ingredients causing spoilage, ingredients may introduce numbers of microorganisms considered undesirable to industrial and regulatory interests.[62] However, spices should not be accepted for processing treatments if they show signs of insect damage or mold growth because of the danger that they may contain mycotoxins.[20] Once treated or otherwise proven to be pathogen-free, spices, like any other food product, must be handled to avoid recontamination. Manufacturing processes such as cleaning, sifting, and grinding provide ample opportunity for cross-contamination to occur, and to be minimized, eg, by application of the HACCP system.[6]

33.10.1 Gas Treatments

Until the early 1980s, the most widely used method to destroy microorganisms in dry food ingredients was fumigation, ie, treatment with ethylene oxide or to a much lesser extent, propylene oxide.[58] Because of the extreme flammability of ethylene oxide, various nonflammable mixtures of ethylene oxide in inert gases were applied. The fumigation treatments were carried out in specially designed vacuum chambers. The concentration range of ethylene oxide used for microbiological decontamination is 400 to 1,000 mg L^{-1}. Under industrial conditions, ethylene oxide treatment reduces the aerobic plate count of spices by 1 to 4 logs depending on the type of spice, the composition of the microflora, and conditions of the treatment.[44] Bacterial spores are only marginally more resistant than vegetative cells. Decrease of mold counts is usually 2 to 3 logs, occasionally more. The rate of destruction of microbial cells depends on the concentration of the fumigant, temperature, relative humidity of the atmosphere in the fumigation chamber, the moisture content of the product treated, the porosity of the product, and the permeability of the packaging material.[68,69] However, because of toxicological considerations, the use of ethylene oxide is now discouraged or even banned for food uses in most countries.[38,103,112]

Decontamination efficacies of ethylene oxide fumigation and other treatments described in subsequent pages can be compared in Tables 33-7 and 33-8.

According to Zhao and Carston,[164] ozone treatment of aqueous slurries of black peppercorns reduced the microbial population by 3–4 log without significant effects on the volatile constituents of the whole peppercorn. Sparging ground black pepper at various moisture levels with ozonized air for up to 6 hours resulted in similar reductions in the viable cell count. However, it caused oxidation of certain volatile oil constituents. Earlier German studies[159] showed also serious flavor changes of various ozone-treated spices, thus, the technological feasibility of ozone treatment for decontamination of spices is very limited.

33.10.2 Irradiation

Ultraviolet irradiation has been tried,[24,40] however, it seems to be unsuitable for commercial purposes, because its penetrating capacity is too low for effective commercial decontamination of dry ingredients.

Unlike UV irradiation, treatment of spices and herbs with Co60 gamma irradiation and machine-produced X-rays or accelerated electrons are viable and safe processes for destroying contaminating organisms in a wide range of products and packaging, with little change of sensory properties.[44,113,119,131,139] The safety and wholesomeness of irradiated foods have been more thoroughly studied than those produced by any other food processing method.[35]

Except for differences related to penetration and eventual dose-rate effects,[73] electromagnetic ionizing radiations and electron beams are equivalent in food irradiation.[152] Depending on the design of the irradiation facility and requirements, products can be treated in bulk or packed forms. Spices are best packaged before irradiation in order to avoid recontamination after treatment (see Chapter 4).[91]

A radiation dose of up to 20 kGy may be required to achieve "commercial sterility" (ie, a count of mesophilic aerobic bacteria of less than 10 cfu g^{-1}) in natural spices and herbs; however, doses of 3 to 10 kGy can reduce viable counts to a satisfactory level (from 10^5–10^7 cfu g^{-1} to less than 10^3–10^4 cfu g^{-1}, see Table 33-7) without affecting quality attributes.[39,46,73,104,105,141,144,146,154] Thermophilic spore-forming bacteria of great importance to the canning industry can be practically eliminated with the same radiation doses as those necessary to cause a sufficient reduction of the mesophilic viable counts (Table 33-9). Bacteria of the family Enterobacteriaceae are relatively radiation sensitive even in dry ingredients, and in most cases a dose of approximately 5 kGy is sufficient to reduce their numbers by a factor of at least 10^3, ie, to undetectable levels.[44] A dose of 4–5 kGy can likewise eliminate molds at least as effectively as ethylene oxide treatment (Table 33-8).

The surviving microflora of spices treated with (pasteurizing) doses of ionizing radiation have lower heat

and salt resistance, and is more fastidious relative to pH, moisture, and growth temperature requirements than that of untreated spices (Table 33-10).[45,47,81]

A *Code of Good Irradiation Practice for the Control of Pathogens and Other Microflora in Spices, Herbs and Other Vegetable Seasonings* has been prepared by the International Consultative Group on Food Irradiation (ICGFI).[66] Although the irradiation of spices and herbs still shows the best results and is the most reliable and versatile technology,[6,57,103] the use of this method remains relatively limited, because of psychological barriers and consequent resistance by consumers (Chapter 4).

33.10.3 Thermal Methods

Because of the heat sensitivity of the delicate flavors and other essential components of many spices and herbs, or some other specific functional properties, a regular heat sterilization cannot be applied. Spice flavor qualities are directly related to volatile oils and/or enzymatically produced flavor components. Therefore, excessive heat, which may denature enzymes or drive off volatiles, must be avoided.[6]

High-frequency and microwave treatments have also little practical utility, because dielectric heating is seriously hampered at the low moisture content of dry commodities.[153] Because of the heterogeneity of the product and the dielectric field, the heating effect is uneven in these materials, which causes adverse changes in sensory quality.[28,29,106]

During the last decade, various other thermal methods have been developed aiming at reducing or eliminating the natural disadvantages of conventional heating. Hot alcohol vapor treatment resulted in the desired antimicrobial effect with whole kernels, ie, whole pepper, but it was not feasible for ground or leafy spices.[106]

The *Sterispice* technique developed in Denmark[100] involves the encapsulation of whole spices with a protein-coating prior to steam heating under pressure. The coating prevents loss of flavors. The heating cycle is different for different spices and takes the heat stability of their flavor components into account.

[a] The mixed seasoning, either untreated or irradiated, was suspended in the ratio of 1:30 in a liquid medium containing various salt concentrations and was subjected to heat treatment at 80°C for 10 minutes or plated without heat treatment. Numbers of colony-forming units were determined by plating dilutions into nutrient agar of identical composition and salt concentration to those of the suspending media. The pH was set at a value of 6.5 and incubation was performed at either 30° or 10°C.

[b] – = not investigated.

Various other, recently established steam heating processes (reported as *MicroMaster* technology in the British literature,[4,5,156] and *MicroControl, EVW,* and *Zellgerm* processes in the German literature[30,31,103,130]) for pasteurization of spices, optimize the processing parameters of batch steam heating for each type of product to ensure low loss of volatiles and minimal color change. The weakest point is still the sensory quality (flavor and color) of leafy products, paprika, and dry vegetable seasonings. Considering the necessity for grinding and blending of steam-treated whole spices, the potential for recontamination compromises somewhat the steam treatment effect, adding the requirement for availability of a *sterile mill* technique.

The *Masterspice* process uses twin-screw extrusion at high temperatures and shear pressures.[151,156] The extruder process is close to an extraction process and its product is completely different from the original spice.[103]

Unlike the situation for the irradiated products, no labeling requirements exist for these alternative methods of decontamination. The Codex Committee on Food Hygiene agreed that consignments of decontaminated spices should be accompanied by a certificate stating the type of treatment to which the product had been subjected.[20] Relevant provisions already exist in regard to irradiated spices in the *General Standard for Irradiated Foods*[18] and for the labeling of consumer products in the *Codex General Standard for the Labelling of Prepackaged Food.*[19]

Labeling of minor ingredients and second generation products produced with irradiated ingredients is a complicated and controversial issue, and views of governments vary significantly from no labeling of "second generation irradiated food," eg, in the United States (US), to labeling of all irradiated ingredients in the food in the case of Denmark. A survey of national regulations, including labeling, has been prepared under the aegis of ICGFI.[66,67]

33.11 MICROBIOLOGICAL CRITERIA FOR, AND MONITORING OF, MICROBIOLOGICAL QUALITY OF SPICES AND HERBS

The safety and spoilage hazards associated with spices added to foods depend on the probability of contamination with disease-causing or spoilage organisms and toxins. Spices are used in a wide variety of foods and are thus capable of introducing microorganisms that may be of no consequence in some products but highly important in others. Therefore, the spoilage and health hazards presented by a spice must be carefully evaluated in the context of the particular use of the spice, with more stringent requirements being reserved for those spices that are added to foods that receive little or no heat treatment, and to cooked foods that are not reheated before eating.[69,110] It is recommended[6] that control of spoilage organisms can be handled strictly between the spice processor and end user for a specific food application and that the count of mesophilic aerobic bacteria should not be used exclusively as a reliable indicator of spoilage potential. According to the Codex *Proposed Draft Code of Hygienic Practice for Spices and Dried Aromatic Plants*,[20] treated and untreated ready-to-eat spices shall be free from *Salmonella* when 10 samples of 25 g are analyzed by appropriate methods of examination ($n = 10$, $c = 0$).

Commodity standards of various countries or organizations usually do not contain specific microbiological criteria for spices and herbs, only macroscopic "cleanliness" specifications. According to the Microbiology Subcommittee of the American Spice Trade Association (ASTA), "routine examination for mold is advised with occasional mycotoxin audits indicated when mold counts exceed typical levels."[6] However, because of the sensitivity of molds to heat and other processing techniques, methods detecting *both* dead and viable biomass of molds, such as the enzyme-linked immunosorbent assay developed by Notermans and coworkers[108,109] give a better index of the "mold history" of spices and herbs than the viable mold counts.

In the spice trade, mesophilic aerobic viable cell counts below a level of 10^3 to 10^4 cfu g^{-1} were traditionally required and accepted as a maximum count of *decontaminated* spices (in German: "entkeimte Gewürze").

33.12 CONCLUDING REMARKS

Most of the world's spices and herbs are grown in tropical developing countries. Under the prevailing conditions of cultivation and harvest, some soilborne microorganisms are inevitably present and inadequate sanitation in primitive harvest, and postharvest conditions may occasionally permit introduction of small numbers of pathogenic bacteria. With demand for herbs and spices increasing, and with today's requirements for safe and consistent food products of high quality, improvement of microbial quality is needed, and the food industry is looking much more closely at the hygiene and safety implications of using these products. In order to conform with the requirements of the food industries in more developed countries, the use of alternative ingredients such as essential oils, oleoresins, and dry dispersed or encapsulated spice extracts will likely grow. Better methods of growing, harvesting, sorting, cleaning, and storage of the raw materials are obviously needed and hazard and control point assessments should support sensible, effective control measures for the spice industry. However, as illustrated by Table 33-2, comparison of microbiological surveys with large numbers of samples in various parts of the world and several years apart,[65,69,113] shows that the ranges and percentage distribution of microbial contamination among samples of specific commodities are remarkably similar and no improvements can be noted. Good manufacturing practice and concepts such as the hazard analysis critical control points must consider the whole process including production of raw materials in their countries of origin. However, the importers' lack of direct control in exporting countries diminishes critical control point opportunities. Therefore, a need for treatments of specific nonextracted spices and herbs to reduce microbiological contamination to a level low enough to satisfy the food industry will remain for a foreseeable time.

The increasing regulatory pressure against the continued use of microbicidal gases and the banning of ethylene oxide treatment in certain regions of the world have given rise to new challenges for alternative treatments. In spite of technical superiority and government approvals, irradiation treatment still has not been widely applied because of fear of adverse consumer reaction. We may well see, however, changes in the consumer's attitude toward food irradiation technologies from which treatment of dry ingredients is one which has the best application potential. A range of new thermal methods are now being promoted. Their general utility is still restricted; however, further optimization of new heat treatment methods and cleaner sources of raw materials brought about by improved techniques at source will result in less severe heat treatment requirements and, in turn, will reduce flavor loss and discoloration.

Antimicrobial activity of some essential oil components of spices has been well documented. Available data suggest that they can be useful adjuncts in food preservation and could have the potential to be used in some food systems to inhibit growth of foodborne pathogens. The intense sensory attributes of essentials oils may be an impediment to their use in some foods. However, this could be overcome if means were found to enhance their activity, for instance, by combination with other preservative factors. A better understanding of the modes of action of the oils may assist achieving these goals. In spite of their "naturalness," the safety concerns of using them need to be investigated further.

CHAPTER CONTENTS

34.1 Introduction
34.2 Production
34.3 Processing/preservation
  34.3.1 Drying
  34.3.2 Hulling and decortication
  34.3.3 Blanching
  34.3.4 Roasting
  34.3.5 Chopping, slicing, shredding, and grinding
34.4 Initial microflora
  34.4.1 Brazil nuts
  34.4.2 Coconuts
  34.4.3 Groundnuts
  34.4.4 Pecan nuts
  34.4.5 Pistachio nuts
34.5 Effects of processing and storage on nut microflora
  34.5.1 Windrowing and drying
  34.5.2 Hulling and decortication
  34.5.3 Blanching and washing in hot water
  34.5.4 Roasting
  34.5.5 Chopping, slicing, shredding, and grinding
  34.5.6 Storage
34.6 Bacterial toxins
34.7 Mycotoxins
  34.7.1 Aflatoxins
  34.7.2 Cyclopiazonic acid
  34.7.3 Other toxins
  34.7.4 Summary
34.8 Microbiological quality and safety
34.9 Legislation
  34.9.1 Microbiological standards
  34.9.2 Mycotoxins
34.10 Concluding remarks
References

34.1 INTRODUCTION

The term *nuts* is commonly applied to a wide range of fruits and seeds, some of which are not nuts in a strict botanical sense.[77] Menninger[65] gives a popular definition as "any hard-shelled fruit or seed of which the kernel is eaten by mankind." Nuts may be used for edible and nonedible manufacturing purposes; for example, in the former category, for production of oils and fats, and in the latter, chemicals extracted are used for plastics, detergents, and so on. The botanical definition, "a hard, indehiscent one-seeded pericarp generally resulting from a compound ovary, as the chestnut or acorn,"[77] is based on morphological features. The acorn, chestnut, and filbert (hazelnut and cobnut) fit both the botanical and the popular definitions of a nut. However, botanically, Brazil nuts are seeds, groundnuts (peanuts) are legumes, and almonds, coconuts, pecans, pistachios, macadamia, and walnuts are all drupes (fleshy fruit with a hard-shelled stone containing the seed).

Nuts originating in temperate zones include almonds, filberts (hazelnuts), walnuts, and sweet chestnuts. Nuts originating in the subtropics include pecans and pistachios, and those originating in the tropics include Brazils, cashews, coconuts, macadamia, and groundnuts. Many are tolerant of a wide range of conditions.

This chapter will use the term "nut" in its broadest sense, but will concentrate on the 11 most important types of nuts or nut products in world production or trade (Table 34-1). The most important nut worldwide is the groundnut. Other commercially important nuts include cashews, filberts, almonds, and walnuts.

Table 34-1 gives production statistics and importing countries for some of the most important traded

Table 34-1 Production and Trade Information for the Eleven Most Important Nuts

Nut	*Botanical Name*	*Production 1994/5 (1000 metric tonnes)*		*Major Producer Countries*	*Main Importing Countries*

[n] India is a large producer of nuts

nuts. The United States (US) is the principal consumer for most nuts, apart from groundnuts. The countries of the European Union (EU) are also important consumers of most tree nuts, and the United Kingdom (UK) is the world's largest importer of groundnuts. Consumption of most nuts is very seasonal, particularly for tree nuts such as walnuts, chestnuts, filberts, and Brazils, with highest consumption of these nuts around Christmas in Western countries. Many other nuts are consumed all year round, particularly if processed into other products. In the US, Europe, and Australasia, most nuts are used in the food processing industry, as ingredients for bakery products, cereals, ice cream, and sweets. For home consumption, they are processed into salted, dry- or oil-roasted forms, or used raw.

Depending on the type, nuts are either traded in-shell or shelled. Cashews for consumption are always retailed shelled, but can be traded on an in-shell basis, prior to final processing. Walnuts and pistachios are almost always traded and sold for consumption in-shell. Almonds are usually traded shelled, filberts and Brazils shelled or in-shell. Macadamias are traded in-shell, but sold for consumption shelled. Groundnuts are usually traded as "hand-picked selected" (HPS). The economic value of nuts is shown in Table 34-2.

Most nuts are extremely high fat commodities, rich in calories because the edible portion of most nuts has a high protein and polyunsaturated fat content. The exception is the chestnut, which, even if dried, contains only 4.1% fat. The fat content in pecans can be as high as 75%. Almonds, pistachios, and groundnuts also have high protein contents, while chestnuts have very high carbohydrate levels. Most nuts are also excellent sources of calcium, phosphorous, iron, potassium, and B vitamins. The proximate analysis of 11 selected nuts is given in Table 34-3.

34.2 PRODUCTION

Nuts are usually produced in large orchards or plantations, with the exception of Brazil nuts. The US is a major producer of almonds, macadamias, groundnuts, pecans, pistachios, and walnuts. Middle Eastern countries are an important source of warm temperate nuts such as almonds, chestnuts, filberts, pistachios, and walnuts. Commercial harvesting of tree nuts is either by hand, or by using mechanical shakers to remove the nuts from the tree, after which they are caught below. Data have been taken from many texts[36,65,77,111-113] and from sources noted in Table 34-1.

Table 34-2 Value in US Dollars of Some of the Most Important Nuts (estimates published in 1997)

Nut	*Dollars, US, per kg*
Almonds	3.4–6.7[a]
Brazils	3.8[a]
Cashews	3.8–6.1[a]
Coconut, desiccated	0.9–1.2[a]
Filbert	3.08
Macadamia	12.1
Groundnut	0.8–0.98[a]
Pecan	3.0–4.6[a]
Pistachio	4.4[a]
Walnut	2.1–3.6[a]

[a] See Reference[14]

Almonds. Over half of the world production of almonds is concentrated in California, US, in the Sacramento and San Joaquin valleys. Other countries producing almonds include Spain with about 25% of the world crop, Italy with around 8%, and Portugal, Iran, Morocco, and Turkey. US production of almonds is highly mechanized.

Brazil nuts. Brazil nuts have generally proved impossible to bring into domestic cultivation. They are still mainly collected directly from wild trees in the forests of the Amazon basin, in Brazil, Bolivia, Peru, Venezuela, and Colombia. Production levels of Brazil nuts are in decline because of falling tree yields. Good quality Brazil nuts are exported, while poor quality nuts are used for production of Brazil nut oil. Brazil nuts are exported in-shell or shelled.

Cashews. Cashews can grow on poor soils, therefore, in many countries cashews have been introduced to protect coastal sand dunes, to utilize wastelands or other poor soils, and to help prevent desertification. Cashews are a very labor-intensive crop to harvest; production of cashew nuts is therefore mainly from farmer smallholdings, and secondly from trees planted for soil conservation purposes. The remainder of the crop is taken from larger commercial plantations. Approximately half of the world's cashew nut production and processing is centered around India and Brazil. Cashew shells contain the corrosive cashew nut shell liquid (CNSL), which makes processing hazardous. Large quantities of raw nuts are also shipped to these two countries for shelling from other countries that lack the capability to safely process the nut. Mozambique is the third largest producer, and production takes place in Tanzania, which also has processing capacity. There has been an increase in production in Southeast Asian countries, with Vietnam, Indonesia, Malaysia, and Thailand producing 15% of the world total in 1991.[16] Small-scale processing is also carried out in each country by individual producers for home consumption or local sale.

Chestnuts. Several types of chestnut are commercially harvested. These include American, Japanese, Chinese, and European (variously known as the English sweet chestnut, the Spanish chestnut, or the French chestnut) chestnuts. The main production areas of the European chestnut are France, Italy, Portugal, Spain, and the UK. In the US, the Chinese chestnut has been cultivated to replace the loss of the American chestnut, which was affected by a fungus, *Endothia parasitica.*

Coconuts. Coconuts are the fruit of a tropical palm. Wild palms are frequently harvested, however, coconut palms can be successfully grown in plantations. The major producing areas lie between 22° N and S of the Equator, in the humid tropics. More than 80% of world production comes from the Indo-Pacific region, with the Philippines and Indonesia the major countries followed by India, Sri Lanka, and Malaysia. Desiccated coconut production is concentrated in the Philippines, Indonesia, and Sri Lanka.

Filberts (Hazelnuts and Cobnuts). Turkey is the center of filbert production (70% of world production). A further 20% is produced in Italy, and 7% in Spain. Production is coastal-based, often on small farms. In Turkey, intercropping is practiced; sometimes sheep and goats pasture under the trees.

Groundnuts. Groundnuts are synonymous with peanuts, the former term more commonly used in developing countries, the latter in developed countries. All groundnuts are now commercially cultivated. India and China account for over 50% of the world's production, followed by the US. However, very little is exported from China or India because of high levels of domestic consumption. In India, most groundnuts are utilized either for groundnut oil production, or as a protein source in cooking. The US is the world's largest exporter of groundnuts while Western Europe, Japan, and Canada are the major importers. In the US, half of the production is for edible nuts, while 25% are exported and the remainder are crushed for oil.

Macadamia. Macadamia nuts are native to Queensland, Australia, but the major producers now are Hawaii, followed by Australia and South Africa. Other producers include Kenya, Guatemala, Brazil, and Malawi. All macadamias are harvested from commercial plantations.

Pecans. Pecans are native to North America, with the southeastern and southwestern areas of the US being the most important production areas. Other major producers include Mexico, Australia, and Brazil. Pecans are produced mainly in large orchards, though some are still collected by forest dwellers directly from the forest floor in Chile and other South American countries.

Pistachios. Pistachio nuts are native to Western Asia. The major production areas are located in Iran, Turkey, and the US. In the Middle East, pistachios are harvested either from wild trees or from orchards.

Walnuts. Walnuts are indigenous to Eastern Asia, South Eastern Europe, and North and South America—the major producers being the US, Turkey, and China. The Persian walnut is the most important commercial type grown. Black walnuts are produced in the US on large farms. In France, Italy, and the US, production is fully commercial and a high proportion is exported. In Greece and Turkey, much of the production from smallholder farms is consumed mainly by the farmers themselves. Germany and Spain are the main importers of in-shell walnuts.

34.3 PROCESSING/PRESERVATION

The processing operations for each nut, and for peanut butter are illustrated in Figures 34-1 through 34-12. Moisture contents, where given, are on a "wet-basis" and, with water activity (a_w), are approximate.[15,49] Flow diagrams are generalized. Details can be obtained from many texts,[36,65,77,111–113] unless otherwise stated. General details of processing methods are given below.

34.3.1 Drying

Drying can be carried out under cover, or in the open, to reduce the moisture content of the nuts. In the former case, hot air or radiant heat from a kiln, or solar drying, concentrating the sun's energy and protecting the crop from rain is used. In the latter case, sun drying is used, with no protection from rain. This can be carried out pre- or post-decortication, on the farm or at the processing plant. Groundnuts are windrowed in the field, after lifting plants, which are inverted to prevent pods from touching the soil and to assist them in drying. Pecans, almonds, and walnuts may be windrowed under the trees prior to collection and mechanical drying.

34.3.2 Hulling and Decortication

Hulling refers to the removal of the outer fleshy part of some nuts. Decortication can be used to describe a general process in which a nut or oilseed is cracked open and the kernel recovered, and secondly to an individual stage in a processing operation in which an enveloping layer or hard shell is removed or separated prior to a more involved recovery process. Words such as dehusking, husking, cracking, splitting, and shelling are also frequently used to describe decortication operations. Both operations may be carried out by hand or by machine.

34.3.3 Blanching

Blanching refers to the removal of the skin (testa) of the nut, either by wet or dry methods. In the wet method, steam or hot water is used to moisten and swell the skin, followed by rubbing to remove the skin. Blanching can be mechanized, using machines with rubber fingers or rollers, or by hand.

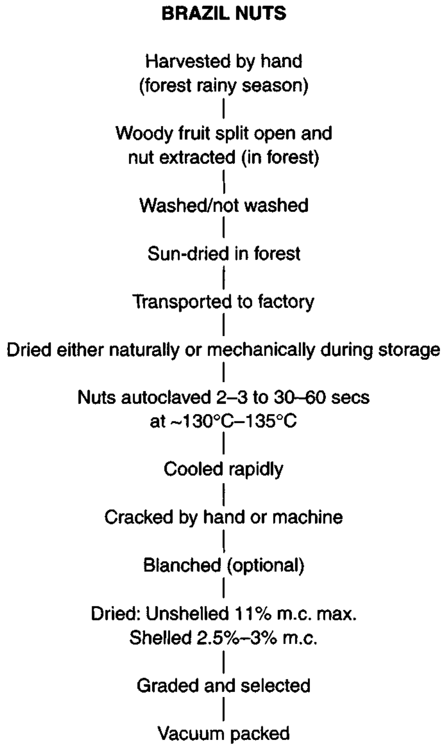
34.3.4 Roasting

Roasting is either carried out dry, using radiant heat, or in oil. Temperatures range from 140°–210°C, for varying lengths of time. Nuts may be dry roasted in air, hot sand, or ashes. Nuts are usually blanched before roasting, to avoid off-flavors from the skin being transferred to the kernel. In some cases, nuts are sand roasted, then shelled and blanched.

Roasting of cashew nuts is a specialized operation because of the presence of CNSL in the shell. Traditional roasting methods allow the oil to escape into the fire and be burnt. Factory-scale methods usually involve collecting CNSL, which is used in industrial processes, including lubricants, brake linings, plastics, lacquers, and antimicrobials.[16]

34.3.5 Chopping, Slicing, Shredding, and Grinding

Decorticated nuts, for example, almonds, are sliced and chopped, with or without prior blanching. Desiccated coconut is made by shredding (disintegration) of the pared kernel (meat) of coconuts. The production process includes pasteurization of the coconut meat at temperatures between 70° and 90°C for up to 10 minutes[30,79] either before or after shredding, and may also involve treatment with sulfur dioxide or sodium metabisulphite solution. The product is finally dried to a moisture content of not more than 3% (w/w). Coconut water is the aqueous liquid enclosed by the kernel of the whole coconut, whereas coconut milk is prepared by aqueous extraction of ground-up coconut meat followed by removal of oil by centrifugation. Many nuts are ground, and then mixed with other products to produce flours, pastes, and butters, for example, groundnuts, almonds, pecans, walnuts. Nut oils may also be extracted by grinding, followed by separation processes.



Note: Rancidity is a problem due to high oil content (67%).

Figure 34-3 Cashew Nuts.

Peanut butter is made from groundnuts by first roasting shelled nuts either by batch or continuous processes. In the former process, nuts are roasted at 160°C for 40 to 60 minutes in a rotating drum, quickly cooled, dry blanched, inspected, then ground and cooled, mixed, and filled into jars. Salt, emulsifiers, and sweeteners may be added at the grinding stage. The product reaches temperatures of 60°–80°C during the grinding process. The final moisture content is less than 2% (a_w <0.1).[49] The continuous process uses a heated airflow over a conveyor belt to achieve the roast.

34.4 INITIAL MICROFLORA

In general, levels of microorganisms on undamaged tree nuts taken at harvest are low because the thick shell of most tree nuts is an important and effective barrier to microbial penetration. The internal surface of a dry, intact nut that has not come into contact with the soil will be virtually sterile. This was demonstrated for coconut by Kajs et al.,[60] by the aseptic removal of flesh and coconut water. Other data have confirmed this for walnuts, pecans, and other nuts.[21,51,64,66] Nuts that become damaged by insects, birds, or poor handling may become contaminated.

It is important to recognize the difference between the more transient surface microflora, and microorganisms that have penetrated the shell and are growing on the kernel. Even if the nut has come into contact with the soil, the internal surfaces may still remain free from contamination. Mold growth on the kernel is unlikely unless the water activity rises to more than 0.7. Appropriate methods should be used to determine the internal and external microflora, by surface disinfection, and the use of semiselective isolation media. In this way, the microbial risks associated with a particular batch can be determined.[78]

A distinction should be made between commercially produced nuts, and those harvested from wild trees. Any nuts allowed to remain in contact with soil for any length of time may suffer insect or vertebrate damage leading to fungal and bacterial penetration. Nuts grown in humid areas are more likely to

become contaminated with fungi than those harvested from drier areas.

In general, the composition of the contaminating microflora will reflect the soil and air microflora of the region from which the nuts are grown, but in addition, the following common components occur. The aspergilli, in particular *Aspergillus flavus*, are ubiquitous invaders of nuts[73,74] and can produce the mycotoxin aflatoxin. High-fat nut products are particularly susceptible to aflatoxin production. Other important fungi include *Penicillium commune, Penicillium crustosum, Penicillium solitum, Penicillium funiculosum, Penicillium oxalicum, Penicillium italicum, Eurotium* spp., and *Aspergillus versicolor*. Toxins expected include cyclopiazonic acid, penitrem A, citrinin, and sterigmatocystin.[43]

Bacteria isolated from nuts include *Pseudomonas, Xanthomonas, Enterobacter, Clostridium, Corynebacterium, Bacillus,*[88] *Salmonella,*[48] and *Escherichia coli.*[21] Harvest date can also influence the microbiological quality of the nut. For example, late season almonds can have lower fungal counts than almonds harvested earlier in the season.[62]

34.4.1 Brazil Nuts

Brazil nuts may lie on the forest floor for weeks before they are harvested by forest-dwellers during

the rainy season. This can allow extensive fungal and bacterial growth to occur.[77] These nuts are particularly susceptible to invasion by *A. flavus* and *Aspergillus parasiticus*.

34.4.2 Coconuts

At harvest, nuts are cut from the palm and left to age on the ground beneath the tree where they become contaminated with microorganisms present in the soil. Animal grazing beneath the palms increases the risk of contamination with organisms of fecal origin, eg, *Escherichia coli* or *Salmonella* species. There is a direct relationship between the length of time for which coconuts are left on the ground and the contamination level.[53] Nuts left in puddles of water are more likely to crack, resulting in leakage of coconut water and encouraging growth of a wide range of microorganisms. Spoilage microorganisms that have been associated with coconuts treated in this manner include *Pseudomonas*, *Xanthomonas*, *Bacillus*, Enterobacteriaceae, *Clostridium*, *Corynebacterium*, yeasts, *Penicillium*, and *Aspergillus*.[88]

Microorganisms isolated from the shells of coconuts included large numbers of various microbial types including *Acinetobacter*, Enterobacteriaceae, *Flavobacterium*, *Microbacterium*, *Micrococcus* species, and yeasts and molds.[60]

34.4.3 Groundnuts

Groundnuts ripen and mature underground. Therefore, the initial microflora will largely reflect the soil microflora, and contamination is almost inevitable. Sequential harvests of groundnuts in the same soil will increase the level of the soil micro-

flora.[69,70] Groundnuts are particularly susceptible to drought stress, either caused by low rainfall or overplanting, often associated with sandy soils. This can cause pod cracking, allowing fungi to penetrate the pod and grow within the kernels.

Systemic invasion of groundnuts by *A. flavus* and *A. parasiticus* has been noted under experimental conditions.[72] *Aspergillus flavus*, which is a common component of the soil microflora[58,59] particularly in groundnut fields,[71] has been detected invading plants from contaminated seed and soil sources, growing throughout the plant from emergence onwards into the developing groundnuts. *A. flavus* was more invasive than *A. parasiticus* under these conditions, however, the fungus grows within the plant cells causing little apparent damage.

Some workers have suggested that fungal invasion occurs from the contamination of aerial groundnut pegs or flowers.[50] Factors that can reduce the incidence of fungal invasion and aflatoxin contamination include rotating groundnuts with other crops that decrease the soil populations of *A. flavus*, cultural practices that remove plant residues from around groundnut plants, preventing drought stress, harvesting at pod maturity, and continuous rapid

drying of groundnuts after harvest. Resistant lines to fungal invasion have been identified. Resistance factors include tannin content, amino acid components, waxy surface, permeability, and cell structure arrangement.[67]

34.4.4 Pecan Nuts

Pecans gathered as they fall from the tree are virtually mold-free, but if they are left on moist ground for more than 1 week many kernels become infected and visibly moldy.[81] There is a direct relationship between the time of exposure and kernel molding. Kernels from orchards undersown with grass are more likely to become moldy than in those without grass. Typical fungi invading the kernels include *Aspergillus*, *Penicillium*, *Fusarium*, *Rhizopus*, *Phomopsis*, *Cladosporium*, and *Alternaria*.[106] Weevil larvae can burrow through pecan shells, providing an entry point and carrying fungal spores into the

kernel. Other contamination sources include rainwater and airborne dust.[107]

Nuts collected from grazed orchards were more likely to be contaminated with *E. coli* than samples gathered from nongrazed orchards.[64] Contamination was related to shell cracking. Nutmeats from whole uncracked pecans soaked in a solution containing *E. coli* did not become contaminated. Twenty-four percent of the whole pecans soaked in water for 48 hours to simulate standing in a rain puddle developed openings that did not completely close when the nuts were redried.

34.4.5 Pistachio Nuts

Pistachios have a dehiscent shell within a nondehiscent fleshy hull. If they are allowed to lie on the floor, contamination can result, particularly if hulls also split. Pistachios can also become contaminated on the tree, if the hull splits early, which is atypical (early splits). Fourteen species of *Aspergillus* have been isolated from Californian pistachios, mainly from early splits. *Aspergillus niger* has been isolated from up to 30% of kernels from early splits. *A. flavus* and *A. parasiticus* are three times more commonly isolated from early splits than from smooth hulls.[33] The earlier the hull splits, the more it shrivels and decays.[35] Mold counts in the range of 10^3–10^4 colony-forming units per gram (cfu g^{-1}) have been recorded for pistachios.[52]

34.5 EFFECTS OF PROCESSING AND STORAGE ON NUT MICROFLORA

The microflora of nuts will often change during processing. Some processes, such as blanching and roasting, may lead to a reduction in the microflora, while others such as washing and drying may lead to the ingress and growth of microorganisms on the nuts. Wet blanching will reduce the microbial load more than dry blanching, where mechanical rubbing alone is used to remove the skin. Cutting and grinding operations may spread contamination throughout a batch.

34.5.1 Windrowing and Drying

Groundnuts are dried after harvest by windrowing (stacking in rows) in the field. Windrowing of groundnut plants has been shown to reduce the level of infection of shells and seeds by up to 13% and 36%, respectively. Fungi such as *Chaetomium, Rhizoctonia, Fusarium, Sclerotium,* and *Alternaria* have been isolated from shells of windrowed groundnuts.[76] Pod-contaminating fungi can invade during the drying process. If rain or high relative humidity (>85% RH) occurs in combination with temperatures of between 25° and 35°C, increased invasion of the seed pod can occur. Damaged or cracked pods are more susceptible to fungal attack. The major hazard with groundnuts is the growth of *A. flavus* or *A. parasiticus* and the production of aflatoxins. Drying delays can allow extended growth of the organism and toxin production.

During sun drying, nuts subjected to periods of rainwater may crack, allowing microbial invasion. While the shells of nuts are still wet, microorganisms enter, aided by the water, through small cracks contaminating the internal nutmeat. The nutmeat may still remain wet even after drying the outside of the nut, allowing the proliferation of microorganisms. The nuts may also become contaminated from insects and animals unless pest control measures have been implemented. Fumigation to kill insects will have little impact on any contaminating microorganisms.

Intact coconuts on the tree contain very few microorganisms, however, after harvest the nuts are often stored in unhygienic conditions prior to processing. Microorganisms grow rapidly in the coconut water where damage has allowed this to become contaminated. During drying of desiccated coconut, fungal growth, particularly of *A. flavus,* can be a problem, leading to aflatoxin contamination of the flesh.

34.5.2 Hulling and Decortication

The incidence of *E. coli* on meats of commercially hulled black walnuts depended on the physical condition of the nuts; apparently tightly sealed shells contained only a few *E. coli,* whereas those with visibly separated sutures and spoiled meats yielded the most. Large numbers of *E. coli* on the hulls of walnuts contaminated the hulling water, nuts were subsequently contaminated through separated sutures. Chlorination of the hulling wash water was ineffective. Heating nuts to 100°C in coconut oil, followed by removal of excess surface oil by centrifugation was found to be most effective.[66]

Processing operations during decortication can lead to the transfer of microorganisms from dirty to clean nuts; effective cleaning of decortication equipment is necessary. *Pseudomonas effusa, Corynebacterium paurometabolum, E. coli, Leuconostoc mesenteroides, Proteus vulgaris, Aerobacter aerogenes,* and

Clostridium spp. were isolated from commercially shelled pecan nuts, whereas bacteria were not isolated from aseptically shelled nuts.[21] Similarly, *Penicillium notatum*, *Aspergillus clavatus*, *A. niger*, *Fusidium* spp. and *Trichothecium* spp., were isolated from the commercially shelled nuts, whereas *A. clavatus* and *Trichothecium* spp. only were present on the aseptically peeled nuts. However, fungal hyphae had penetrated both types of nuts.

34.5.3 Blanching and Washing in Hot Water

Blanching processes after decortication will reduce the microbial load considerably. Several nuts including almonds may be processed without any washing or dipping stages, although they will undergo dry blanching. Chlorine in wash water will have little direct effect on microorganisms because of the high levels of organic matter present.

Pecans. Pecans prior to sale are either conditioned in steam or chlorinated water followed by a wash in boiling water. This treatment makes the kernel more pliable and less likely to break during shelling. The US Food and Drug Administration (FDA) requires in-shell pecans to be dipped in almost boiling water for several minutes to destroy *E. coli* and other bacteria. The microbial level will be reduced considerably during these operations; however, some microorganisms may still survive. These treatments may be inadequate to consistently destroy salmonellae in highly contaminated in-shell nuts.[18,21,87]

Other Nuts. Brazil nuts are also boiled in water for short periods and sometimes blanched. Both boiling and blanching will reduce considerably microbial levels. Chestnuts are dipped in water at approximately 50°C, this relatively low temperature is unlikely to affect contaminating organisms to any great extent.

34.5.4 Roasting

The extreme temperatures of dry or oil roasting will reduce the microbial load considerably; however, heat-resistant spores may survive. Some reduction in mycotoxin level may occur; reductions of between 40% to 80% in aflatoxin concentration have been noted for groundnut products[89] and for pecans. Drying also occurs during roasting; further microbial growth post-roasting is unlikely, unless products are stored inadequately.

34.5.5 Chopping, Slicing, Shredding, and Grinding

Cutting and chopping operations will spread contamination throughout a batch; product-cutting machinery and lines must be kept scrupulously clean to avoid this. Contamination with *Salmonella* has been a particular problem in the commercial manufacture of desiccated coconut.[48] According to a report published in 1969,[4] *S. senftenberg* was a frequent contaminant of desiccated coconut. In a survey of foods to study the effect of an improved method for detection of salmonellae, published in 1992, 3 out of 12 samples of desiccated coconut were positive for *S. senftenberg*.[28] A further study of retail samples of many foods in 1990–1991 showed that of 185 samples of imported coconut 4% were contaminated with salmonellae but the serotype(s) present were not reported.[70]

Peanut butter is a shelf-stable product, under normal storage conditions, with a final water activity below 0.2. Roasting and grinding operations heat the nuts, reducing the microbial load considerably, as well as drying the product. Any further microbial growth is unlikely, unless water is allowed to re-enter the retail packs after processing. The heating process may also reduce the levels of any contaminating mycotoxins.[89]

34.5.6 Storage

Groundnuts bulk-stored at ambient temperatures under modified atmospheres accumulated less aflatoxin than those under conventional storage. Other fungi are able to grow and cause physical deterioration of seeds.[108] The survival of *E. coli* on in-shell pecans and its destruction with propylene oxide has been studied.[17] *E. coli* survived longest on low-moisture pecans stored at 0°C. Death was rapid in the nut meat and the inner tissue but not on the shell. The effects of 0–800 μg propylene oxide kg^{-1} at 20°, 30°, and 37°C were evaluated under relative humidities of 0% to 97% for 4 to 16 hours exposure times. Propylene oxide was more effective at increased temperature and relative humidity and longer exposure times. Up to 400 μg propylene oxide kg^{-1} may be required to disinfect highly contaminated pecans. The mold population of almonds may decline during storage at 25°C, but not at 5°C, during storage for up to 385 days. Members of the *A. niger* group survived better than most other organisms, consequently increasing in proportion isolated with time of storage; the greatest decline occurring with species of *Peni-*

cillium and *Cladosporium*.[62] The greatest decline in population occurred during the first 60 days.

34.6 BACTERIAL TOXINS

Two outbreaks of botulism were traced to botulinum type A toxin found in peanuts packed in glass jars. Twenty-three of the 90 bottles of the same lot number in the manufacturer's warehouse also contained the toxin. This was the first case in which botulinum toxin was detected in food in Taiwan.[20] The largest outbreak of botulism in the UK in the 20th century was attributed to hazelnut yogurt. The outbreak occurred in 1989 when 27 people became ill and one died. Toxin production did not occur in the yogurt because of the low pH, but the type B toxin had been produced in the hazelnut puree, which had been inadequately processed before addition to the prepared yogurt.[68]

34.7 MYCOTOXINS

Many reviews and surveys have been published on the incidence of mycotoxins in foods and feeds.[19,29,44,56,75,93,110] Most surveys are not country-attributable, in that they comprise data collected from imported products of undisclosed origin. In addition, a large number of individual studies have been conducted on the incidence of individual mycotoxins in particular crops, and factors that affect their production. A selection of survey data is summarized in Tables 34-4 and 34-5.

34.7.1 Aflatoxins

The aflatoxins, produced by *A. flavus*, *A. parasiticus*, and *Aspergillus nomius* are the most common mycotoxins found in nuts and nut products. Aflatoxins were first detected from samples of groundnut meal imported into the UK.[80] Surveys by the US FDA indicate that aflatoxins have been isolated most commonly and at highest levels from groundnut products and groundnuts, followed by imported Brazil nuts and pistachios.[75] They were found occasionally in US-produced almonds, pecans, walnuts, and sunflower seeds. These surveys did not find aflatoxin in cashews, filberts, or macadamias.

Data collected by the joint Food Contamination Monitoring Programme of the Food and Agriculture Organisation/World Health Organisation/United Nations Environmental Programme (FAO/WHO/UNEP) from a range of countries also indicated that groundnuts and groundnut products were the most frequently contaminated nuts, and to the highest levels,[56] followed by pistachios and Brazils. Other surveys have detected aflatoxins in almonds, Brazils, groundnuts and groundnut products, pecans, pistachios, and walnuts.[92,93,96]

For reasons outlined above, most research and screening studies have focused on aflatoxins in groundnuts. Aflatoxins can be produced in the field, during drying, and under storage conditions. They have been detected in groundnuts from all producing regions.[95] Isolates of *A. flavus* taken from groundnuts have been reported to be more likely to produce aflatoxins than those taken from any other commodity, with up to 96% of groundnuts isolates toxigenic, compared with 49% of sorghum and 35% of rice isolates.[82] A seven-year (1982–1989) survey of aflatoxin in peanut butter taken from retail packs indicated that 74% of 2,510 samples were positive for aflatoxin, with 8.6% of positive samples containing between 20–50 $\mu g\ kg^{-1}$, and 2.2% above 100 $\mu g\ kg^{-1}$.[45] Almost 10% were above the US FDA action level of 20 μg total aflatoxins kg^{-1}, the majority in the years 1986–1987. The authors concluded that their findings could be used, in conjunction with other studies, to support a reduction in the 20 $\mu g\ kg^{-1}$ US action level.

In surveys of pistachios in California conducted over several years in 11 orchards, 60% of orchards had pistachios contaminated with *A. flavus*.[34] Only 0.7% of nuts within an orchard were infected with *A. flavus*, however, and 0.1% with *A. parasiticus*; both organisms mainly associated with early splits. In pistachios, the shells of most nuts split prior to harvest; in early splits, the outer hull also splits open, exposing the kernel to infestation. Aflatoxins were mainly associated with rough-hulled early splits, Navel orangeworm-infested and, to a lesser extent, bird-damaged kernels. Other surveys indicated similar data for Californian pistachios.[91,97] Aflatoxin contamination has also been reported in pistachios from Iran.[41] Aflatoxins can be produced in pistachio hulls, although at lower levels than in kernels.[31,34] This has implications for the use of hulls and other pistachio waste as components of animal feeds. Import data for groundnuts into the US indicate that monitoring and control programs are effective in reducing the risk of contaminated products entering commercial channels, but that contamination can occur in many producer countries. In summary, groundnuts, groundnut products, Brazil nuts, and pistachios represent high-risk commodities for aflatoxin contamination; almonds and pecans a lesser risk.

34.7.2 Cyclopiazonic Acid

Cyclopiazonic acid (CPA) has been detected in US groundnut crops.[63] Aflatoxins were detected in both the loose-shell and sound mature kernel (LMK and SMK) fractions, although at lower levels in the SMK portion, whereas CPA was detected mainly from the LMK fraction, at up to 6,525 μg kg^{-1}.

34.7.3 Other Toxins

Ochratoxin A has been detected in visibly moldy[86] and other groundnuts,[105] and in coconut.[114] Penitrem A has been produced in pure culture using isolates of *Penicillium crustosum* taken from pistachio nuts, but not in the natural situation.[37] Sterigmatocystin was detected in pistachio nuts from Californian orchards.[90]

Table 34-5 Contamination of Nuts by Other Mycotoxins

Commodity and toxin	*% of Nuts Contaminated*	*Sample Contamination Level, μg kg⁻¹*	*Country*	*Reference*
Cyclopiazonic acid				
Groundnuts	19	Sound mature kernels, range 32–130	US	63
	77.8	Loose mature kernels, range 32–6525	US	63
Ochratoxin A				
Coconut	12	50–205	Egypt	114
Groundnuts	4.9		German imports	61
Zearalenone				
Walnuts	1 sample	125	Egypt	2
Pecans	1 sample	Detected	US	85
Sterigmatocystin				
Pecans		20,000 (single half kernel basis)	US	84
Alternariols				
Pecans		Alternariol monomethyl ether (AME) and Alternariol (AOH) detected in discolored kernels	US	83

In a study of mycotoxin contamination of filberts and walnuts,[2] although aflatoxin was detected in both walnuts and filberts, and zearalenone in walnuts (Tables 34-4 and 34-5), citrinin, ochratoxin A, patulin, sterigmatocystin, T-2 toxin, and diacetoxyscirpenol were not detected. In another study, almond, cashew nut, chestnut, filberts, pistachio nuts, and walnuts were analyzed for the same range of toxins; aflatoxin was detected in chestnuts but no other toxins were detected in any of the other nut types.[1]

34.7.4 Summary

Aflatoxin production is associated with oilseeds and other commodities with a high fat content; nuts are therefore particularly susceptible. Aflatoxins are mainly produced under warm conditions and, therefore, are more likely to occur in nuts from countries with a warm temperate, subtropical, or tropical climate.

Both the growth pattern of the nut and the agricultural practices of producer regions can influence contamination. For example, nuts that grow in the soil (groundnuts) and those that may remain on the soil after maturity, allowing kernels to undergo wetting and drying cycles (Brazils, some almond crops, some walnut and pecan operations), can become contaminated. Other problems are associated with early splitting hulls or shells, which expose the kernel while on the tree (pistachios and almonds); insect- or bird-damaged nuts, which allow entry points for fungi; and slow drying of nuts once harvested, allowing continued growth of fungi and toxin production.

34.8 MICROBIOLOGICAL QUALITY AND SAFETY

Control of microbial contamination, and the potential production of toxins (particularly aflatoxin) in nuts can be achieved by a selection of strategies. Any form of damage can allow the ingress of spoilage organisms. Preharvest strategies include breeding for resistance to insect pests and to fungal invasion, and, if the fungus penetrates, for resistance to the production of the toxin in tissue; manipulation of the growing environment may be used, including avoidance of drought stress in the case of groundnuts. With tree nuts, delays should be avoided between nuts falling to the ground and being picked up. The drying process should be rapid, and uninterrupted. Mechanical damage should be minimized.

Measures to reject nuts contaminated with aflatoxins usually rely on some form of grading. Nuts that are obviously damaged by insects or vertebrates, or that are moldy or immature should not be harvested. Aflatoxin testing of batches at intake is necessary, and loads should be segregated according to the level of contamination. Stores for nuts preprocessing should be clean and dry. Once shelled, more care is required for storage of nuts as they are more susceptible to fungal and insect attack. It is particularly important to avoid moisture uptake by the kernels. Sorting and segregation procedures are required preprocessing. Color sorting, either electronic or manual, can be used to detect some contamination. Mold-infected nuts are often lighter than healthy nuts; in this case, flotation techniques can be used. The storage environment can be manipulated by the use of modified atmospheres, barrier films, and fumigants.[38–40] Processing operations involving heat (roasting, grinding) may reduce the level of a mycotoxin in a batch.

Control measures to prevent bacterial growth and cross-contamination of processed and raw nuts require procedures for maintaining the sanitary quality of the plant and processing equipment. Of particular importance are procedures involving slicing, chopping, or grating of nut flesh, where contamination of a small proportion of nuts can be spread throughout a batch, if grading procedures are inadequate, and equipment is not cleaned frequently.

Codes of hygienic practice for the production of tree nuts[23] and of desiccated coconut[22] have been published. At harvest, if good manufacturing practices (GMP) are followed, nuts are harvested with minimal damage and dried to a water activity less than 0.70, it should be possible to store them for considerable periods of time, as long as they are not exposed to temperature abuse during storage.[3] If the method of harvesting and subsequent handling were based on the combination of GMP and the hazard analysis critical control point (HACCP)[54] concept, then the quality of nuts and all subsequent products would be improved.

34.9 LEGISLATION

Legislation concerning microbiological or mycotoxin standards varies from country to country. Some countries have horizontal (general) standards, others have vertical (specific) standards for groups of commodities.

34.9.1 Microbiological Standards

UK

The UK does not have specific microbiological standards for nuts or nut products. The Food Safety Act 1990 prohibits the processing or sale of food that is not of the quality demanded by the consumer and prohibits processing food in such a way that it becomes harmful to health. These regulations cover the contamination, poor handling or treatment of food, and food ingredients.

EU

The EU does not have specific regulations relating to the microbiological quality of nuts. General hygiene directives apply to foods in these cases.

US

Specific regulations regarding the microbiological quality of nuts and nut products are not laid down. Compliance Policy Guide 7112.11[102] recommends legal action to be taken when *Escherichia coli* at a level of at least 0.36 per gram (determined by most probable number technique and IMViC confirmed) is found in one or more subsamples of nuts.

Codex Alimentarius

This international body has laid down several standards relating to nuts including general hygiene requirements for unshelled pistachios[24] and grated desiccated coconut.[25] When tested by appropriate methods, these products should be free from hazardous microorganisms at harmful levels, and should not contain substances produced by microorganisms at levels that would be harmful to health. Additional requirements for desiccated coconut contained in the recommended international code of hygienic practice[22] state that the product should be free from *Salmonella* and other pathogenic organisms, and toxic substances originating from microorganisms, with a maximum moisture content not exceeding 3%. A similar code of hygienic practice for tree nuts gives similar recommendations, omitting *Salmonella*.[23]

34.9.2 Mycotoxins

Legislation for mycotoxins, mostly for aflatoxins, exists in 77 countries.[104] At least 27 countries have regulations specifically for nuts or nut products, mostly for groundnuts and groundnut products, and in most cases these are more stringent than regulations for other foods.[93,103,104] If specific legislation does not exist in a particular country, then the legislation for general foods applies. Tolerances generally fall in the range 5–10 μg kg^{-1} for aflatoxin B1, and 10–20 μg kg^{-1} for total aflatoxins, depending on the country. Information on some specific countries or groups is contained below.

UK

The Aflatoxins in Nuts, Nut Products, Dried Figs, and Dried Fig Products Regulations 1992[6] specifically prohibit the import from non-European Community (EC) countries of these products, unless through designated places of entry. The analysis of the import itself must be according to specified sampling and analytical procedures. The maximum permitted total aflatoxin level is 4 μg kg^{-1}, at point of sale. If products are to be processed further then 10 μg kg^{-1} is the maximum import level.

EU

No legislation currently exists for foodstuffs, only for animal feed components.[26,27] However, a working document, Draft VI/1669/97 revision 8, effective January 1999, concerning groundnuts, nuts, and dried fruits, and their processed products has been prepared for discussion. Nuts for direct human consumption may not contain more than 2 μg kg^{-1} of aflatoxin B1, or 4 μg total aflatoxins kg^{-1}. Groundnuts that will be sorted or physically treated prior to human consumption may not contain more than 8 μg kg^{-1} aflatoxin B1, or 15 μg total aflatoxins kg^{-1}. Nuts and dried fruit that will be sorted or physically treated prior to human consumption may not contain more than 5 μg aflatoxin B1 kg^{-1}, total aflatoxins 10 μg kg^{-1}. Otherwise, regulations in individual member countries apply.

US

The FDA has established maximum aflatoxin levels in various nut and nut products in Compliance Policy Guides (CPGs). Accordingly, legal action may be taken if aflatoxin levels above 20 μg kg^{-1} (with aflatoxin B_1 identity confirmed by chemical derivatization) are found in groundnuts and groundnut products, Brazil nuts, and pistachio nuts. This is covered in CPGs 7112.02, 7112.07, and 7112.08,[98,100,101] respectively. Other nuts must comply with the guidelines laid down in CPG 7112.06,[99] which states that legal action is recommended if aflatoxin levels are above 20 μg kg^{-1} (with aflatoxin B_1 identity confirmed by chemical derivatization and negative ion chemical ionization mass spectrometry).

34.10 CONCLUDING REMARKS

The major microbiological problems of nuts occur because of mold and mycotoxin contamination. Bacterial contamination presents fewer problems, and is more common in highly processed nut products, for example, *Salmonella* contamination of desiccated coconut.

Contamination with aflatoxin is the main food safety hazard of nuts. Soil contamination, slow drying, or damage are the major predisposing factors determining if contamination will occur. Nuts that grow in the soil (groundnuts), or may lie on the soil after falling from the trees (pecans, walnuts, pistachios, Brazils), may therefore present the greatest risk. Pistachios are a special case in that the nut kernel can be exposed to fungal attack if the hull splits early or is damaged. Brazils are potentially a high-risk crop, because they are harvested from the floor during the rainy season, taking some time to dry, in conditions of high temperature and relative humidity. If plantation management could be achieved, then this would help to improve the ease of harvesting, and reduce the risk of nuts remaining on the ground for too long.

As analytical methods improve and the detection limits for aflatoxin fall, importing countries tend to set stricter limits for aflatoxin. This has serious implications for producer countries, many of which are developing countries.

Most nuts or nut products are consumed without cooking, which in any case has little effect on aflatoxin. Irradiation procedures are not commonly used, and also have no effect on mycotoxins at practical irradiation doses. Mycotoxins must therefore be removed by other means. Selection and grading procedures are still the most common method of removal of the mycotoxin hazard.

Selection and grading procedures need to be designed for each nut, based on a known defect associated with mycotoxin contamination, so that visual selection or machine grading can occur efficiently. Examples include color sorting for groundnuts. Effective rapid detection methods are required for both fungal and bacterial contamination, so that contaminated nuts can be identified more easily in the factory.

HACCP procedures must be integrated into the whole production, transportation, and processing chain, as has happened for other cropping systems, for example, horticulture. Mold and mycotoxin contamination has usually occurred by the time the product has reached the processing factory; the only effective way to control the hazards and minimize losses for the producer is to identify the Critical Control Points along the whole chain and to implement control measures.

Nuts are relatively expensive commodities and many are rich in micronutrients. The potential for adding value is enormous, particularly in the health food market in the industrialized West. These new products themselves may present food safety challenges that must be met to ensure that foods produced are safe.

35.1 INTRODUCTION

Sugars, the "sweet" components of plants, are formed during photosynthesis from the three basic elements carbon, hydrogen, and oxygen. Generally speaking, and in particular for consumers, the term sugar is clearly associated with sucrose. Sucrose is in fact widely distributed in nature and therefore easily manufactured in large quantities and frequently used as raw material in food products. Other sugars, however, such as dextrose, lactose, fructose, or polyols, such as mannitol, sorbitol, xylitol, and maltitol, also play an important economic role. Sucrose is manufactured from two main agricultural crops, sugar cane in subtropical and tropical climates and sugar beets in moderate or continental climates. These two sources account for 99% of the worldwide sucrose production, while a small amount is produced from sugar palms (1%), sweet sorghum (0.05%), and maple trees (0.01%).[41]

Mixtures of dextrose (glucose) and fructose (also called levulose) obtained by hydrolysis of sucrose are termed invert sugar. Fructose is obtained from solutions of invert sugar by means of ion-exchange separation or from high-fructose corn syrup after purification. Dextrose is obtained from complete hydrolysis of starch. Polyols are present in fruits, vegetables, and cereals in low concentrations. Extraction is, however, not economical, and the different sugars are manufactured by hydrogenation of easily available carbohydrates, maltitol from high-maltose glucose syrups, sorbitol from dextrose syrups, mannitol from fructose, and xylitol from xylose derived from xylan present in hemicellulose. Lactose or milk sugar is found in milk and produced commercially from whey. Sugar syrups are concentrated aqueous solutions of sugars in liquid form, which are either obtained from cane or beet sugar, from sap of the maple tree, or by acid or enzyme hydrolysis from starches of different plants such as potato, corn, or wheat.

Specifications for sugar, dextrose, lactose, fructose, and for glucose syrup are given in the Codex

Standards 4-1981, 7-1981 or 8-1981, 11-1981, 102-1981, and 9-1981, respectively.[21]

Honey is naturally produced by honey bees, mainly from nectars of flowers. Its sugar composition, consistency, and color vary according to the plant of origin; specifications are given in the Codex Standard 12-1981.[21]

Cocoa powder is prepared by transformation of cocoa press cake obtained from mechanically pressed cocoa nibs or liquor to partially remove the fat. Chocolate is manufactured by mixing one or more of the following base components: cocoa nibs, cocoa mass, cocoa press cake, or cocoa powder with other optional raw materials, such as dairy ingredients, sugar, or flavorings. Standards for semifinished products, such as cocoa nibs, masses, press cake, or powder used to manufacture cocoa and chocolate products, are given in the Codex Standard 141-1983.[21] Chocolate and cocoa represent a rather uniform group of products, which are defined in the Codex Standards 87-1981 and 105-1981.

In contrast, sugar and chocolate confectionery products form a very heterogeneous group of products such as bars, blocks and bonbons, boiled sweets, toffees, fudge, fondants, jellies, pastilles, marshmallows, and chewing gum and also very local and traditional products manufactured in different regions of the world. All of these products are manufactured applying different technologies and a very wide range of raw materials and ingredients.[94] Specifications for composed and filled chocolate and cocoa butter confectionery are provided in the Codex Standards 142-1983 and 147-1985.[21]

A major characteristic of most of the products covered in this chapter is their low water activity (a_w ≤ 0.65), which prevents the growth of pathogens. Spoilage by osmophilic yeasts or xerophilic molds may, however, occur. In view of their properties, which lead to rather different microbiological issues, the above mentioned products will be subdivided into four groups: sugars, sugar syrups, honey, and cocoa, chocolate, and confectionery products. The microbiological aspects will be discussed individually.

Products often categorized as confectionery but characterized by high water activities will not be discussed in this chapter. These include products such as sponge-cakes filled with cream, which are related to pastry and dairy products and have microbiological problems that are quite different from those discussed in the present chapter.

35.2 SUGARS

35.2.1 Composition

Sucrose is a disaccharide composed of one molecule of α-D-glucose linked with a molecule of β-D-fructose. White sugar is purified, crystallized, sucrose (min. 99.7%) with less than 0.1% moisture. Depending on the level of purification, brown or soft sugar contain lower concentrations of sucrose (88% to 92%) and have a higher moisture content (2% to 4.5%). Invert sugar is a hygroscopic sugar composed of equivalent percentages of fructose and dextrose as well as residual sucrose in quantities depending on the extent of hydrolysis.

Sucrose or invert liquid sugars are concentrated aqueous solutions frequently used in the food and pharmaceutical industry. Product composition and characteristics may vary from one supplier to another, but typically sucrose liquid sugars have a solids concentration of 67% to 68% compared with 73% to 77% for invert liquid sugar.

Dextrose or D-glucose is a monosaccharide commercialized as crystallized dry powder (min. 99.5%) either in the anhydrous or the monohydrated form with a residual moisture content of maximum 2% and 10%, respectively. Fructose is a monosaccharide with a keto structure forming very hygroscopic anhydrous crystals and is commercialized as dry powder (max. moisture 0.5%). The polyols sorbitol, mannitol, xylitol, and maltitol are commercialized as crystalline powders. Sorbitol and maltitol are also commercialized as aqueous solutions.

Lactose is a reducing disaccharide composed of one molecule of glucose and one molecule of galactose. Normally the monohydrated α-isomer is produced for commercialization as crystalline powder with not more than 6% moisture.

35.2.2 Initial Microflora

The initial microflora of the different agricultural crops may differ greatly depending on the climatic conditions under which they are grown.

Sugar cane (*Saccharum officinarum)* is grown between 15° and 30° N latitudes, covering parts of Brazil, Cuba, Mexico, South Africa, India, China, Australia, and Hawaii. The ideal climate should be warm (30°C) with an adequate moisture during the growing season and cool but frost-free (10°–20°C) and dry during the harvesting season.[11]

The numbers of microorganisms found on the surface of the cane or in the liquid accumulating in axils of leaves will depend on these climatic conditions and organisms belonging to numerous genera such as *Bacillus*, Enterobacteriaceae, *Pseudomonas*, *Lactobacillus*, yeasts, and molds have been described.[137] More specific studies showed that populations of bacteria and fungi in the liquid found in leaf sheaths were related to its sugar content and pH.[9,38]

Ashbolt and Inkerman[3] have shown that the pink sugar cane mealybug, *Saccharococcus sacchari*, is common in countries growing sugar cane. It is found between the leaf sheath and the stem of the plant and excretes an acidic honeydew (about pH 3) favoring the development of acetobacter-like bacteria (for which the mealybug is the vector) and acidophilic yeasts. After die-off of the insects, less acid-tolerant genera such as *Erwinia* spp. and *Leuconosotoc* spp. become dominant. In the case of heavy infestations by the insect, the high quantities of exudate accumulating in the leaf sheath pocket will lead to problems during sugar production. Damage caused by the cane borer (*Diatraea saccharalis*) results in invasion of internal tissues and heavy multiplication of microorganisms. Of particular importance is *Leuconostoc mesenteroides*, which produces dextran in storage tissues of the plant. Similar observations have been made for cane varieties with growth cracks, with damage caused by overburning before harvest, or in the case of plants suffering from freezing damage.[19]

Sugar beet (*Beta vulgaris*) is the second most important sugar crop and is grown in numerous countries, mostly between 30° and 60° N latitudes. The microflora found on the external part of beets reflects that of the soil and genera such as *Pseudomonas*, *Arthrobacter*, *Erwinia*, and *Streptomyces* as well as mesophilic and thermophilic *Bacillus* spp. and *Clostridium* spp. have been described.[16]

In the case of palms (eg, *Phoenix sylvestris*, the wild date palm) *Lactobacillus* spp. and yeasts represent the major part of the microbial flora in inflorescences. *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Acetobacter aceti*, *Acetobacter rancens*, *Acetobacter suboxydans*, *Leuconostoc dextranicum*, *Micrococcus* spp., *Pediococcus* spp., *Bacillus* spp., and *Sarcina* spp. have been isolated and identified from freshly collected sap.[127] The presence of nutrients and the neutral pH of the sap favor growth and fermentation by these organisms.

In the case of whey used for the production of lactose, the initial microflora depends on the origin of the whey and on the initial processing steps (cheese manufacturing, whey storage, transport, and processing) and is described in the chapter on dairy products.

35.2.3 Effect of Processing

Cane Sugar

Harvesting techniques can vary and mature cane may be harvested as such or after burning to eliminate leaves, manually using cane knives (machetes) or mechanically, sometimes with immediate chopping into pieces or billets of about 30 cm length, thus increasing the percentage of exposed surfaces.[33] The incidence of *L. mesenteroides* increases dramatically after burning or harvesting because of recontamination by harvesting tools or insects such as wasps, attracted by the sap.[9,39,135,136] Development of this and other acid-forming organisms is the major cause of deterioration of the quality of cane sugar resulting from the degradation of hexoses and the production of invert sugar, lactic acid, acetic acid, and dextrans, causing losses of sugar of the order of 0.5% to 1.5% depending on the climatic conditions.[124,138]

Reduction of delays during transport from the field to the factory is the major way of preventing deterioration and thus sugar losses of harvested cane. Trials applying biocides or electromagnetic wave energy to delay microbial growth on and inside the sugar cane stalk were not very successful.[33] Sugar cane is further processed into products such as raw or refined sugar (sucrose) and molasses.[138] A simplified flow diagram summarizing the processing steps from the sugar cane stalks to raw sugar and further to refined sugar is given in Figure 35-1.

Cut cane is shredded and passed through a mill composed of rollers, with extraction water flowing in the opposite direction. The raw juice with a temperature normally between 25° to 30°C, rich in sucrose, inorganic and organic salts, amino acids, micronutrients, and with a pH of 5.0 to 5.6 is an ideal medium for microorganisms. However, normally only a few microorganisms predominate and selective enrichment of *Leuconostoc* spp. and other acid-producing organisms occurs. Development of *L. mesenteroides* leads to the transformation of sucrose into dextrose and fructose and to the production of dextransucrase causing polymerization to dextran. This causes sugar losses, and the polysac-

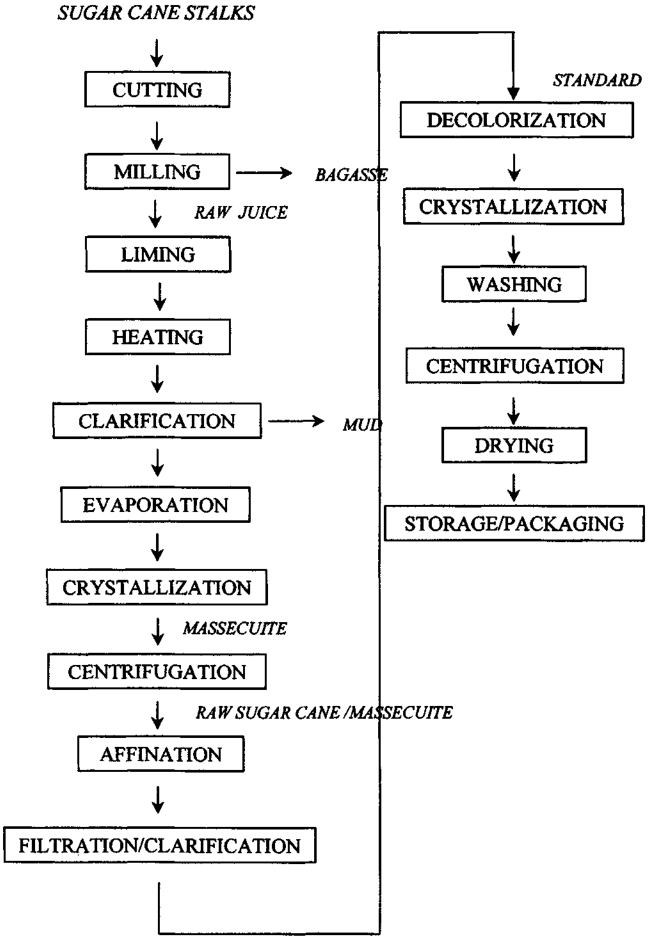

Figure 35-1 Flow Diagram of Cane Sugar Processing.

charide has an adverse effect on further processing steps and on the quality of sugar crystals. Methods for the enzymatic (dextranase) degradation of dextrans already formed by *Leuconostoc* spp. have been successfully developed, allowing the hydrolysis of 72% to 95% of the polysaccharides and improving sugar recovery from contaminated juice.[33]

The extent of recontamination of the raw juice with Enterobacteriaceae or yeasts depends largely on the hygienic status of the mill. Effective housekeeping, sanitation, and use of appropriate biocides are important to minimize sugar losses before further processing.[40] Work has been focused on the inhibition of cane or fungal invertase activity using biocides such as benzoic acid, formaldehyde, or sodium metasilicate.[19,34,57] During subsequent clarification, the pH is raised to 8.0 by the addition of lime and the juice is heated to 80° to 100°C to destroy vegetative microorganisms. Sedimentation and filtration are then used to eliminate precipitates and suspended solids, which are removed in the filter cake mud obtained during pressing and usually recycled. The only viable microorganisms that usually remain in the pressed juice are spores, including those of thermophiles.[19] Residual dextran formed during earlier stages may cause problems during subsequent processing steps, ie, clogging of pipes and interference during evaporation and crystallization of the concentrated juice at 60°C from a supersaturated solution (a_w of approximately 0.85 to 0.88). The concentrated sugar suspension, the so-called massecuite, is cleaned by centrifugation to separate sugar crystals from molasses consisting of sucrose, invert sugar, organic acids, amino acids, nitrogenous compounds, minerals, polysaccharides, and water.

Raw cane sugar used as raw material in the refinery has a pH of 5.0 to 6.0, a water activity of about 0.65, and a sucrose concentration between 95% to 99% with about 0.5% of molasses deposited as a film on the surface of crystals. The microflora of this product consists of spores of *Bacillus* and *Clostridium* spp. that survive thermal processes[19] and osmophilic yeasts and molds. Contamination by these osmotolerant yeasts, such as *Zygosaccharomyces rouxii*, *Hansenula* spp., *Pichia* spp., and *Candida* spp., often occurs in storage tanks for syrup or molasses or by wet sugar residues that support growth of these yeasts in the production lines. Several of these yeasts are also thermotolerant.[2,6,139] Molds such as *Aspergillus* spp., *Penicillium* spp., and *Monilia* spp. are the most common and are often of airborne origin.

Raw cane sugar may occur with a water activity of up to 0.83, which reflects inadequate centrifugation and/or moisture uptake resulting from high humidity conditions. Growth of yeasts is then favored in the molasses film and may cause important economic losses because of hydrolysis of sucrose to form invert sugar. Mold spoilage, however, seems not to be of major concern probably because the oxygen content in the silos used now is normally insufficient to support growth, in contrast with the situation in jute bags, which have been used frequently in the past.

Transformation of the raw cane sugar into crystalline sugar during refining consists of several steps, which may influence the composition of the microbial population of the finished product. During affination raw sugar and molasses are separated by centrifugation and washed with water under high pressure while centrifuging, resulting in the elimination of residual molasses and microorganisms.

The washed sugar is then dissolved in hot water to obtain a syrup of about 70°C/60% solids, mixed with lime and carbon dioxide or phosphoric acid to precipitate impurities, including bacteria, which are then removed by filtration or clarification. Ash is removed by deionization and colors by filtering hot solutions through charcoal beds and ion exchange resins. After evaporation and crystallization, sugar, a product with a low number of microorganisms, <1,000 cfu g^{-1} and frequently <100 cfu g^{-1}, is obtained after drying.[101]

Beet Sugar

Sugar beets are summer or winter crops depending on the climatic conditions of the region. Delayed harvest normally allows an increase in the sugar content because of accumulation of sucrose. However, at the same time the raffinose content begins to increase. Topping (cutting of leaves and crowns), cleaning, and disposal of tops are the major operations involved during harvesting. Harvested beets are then often stored in piles on the fields for between several days and months before further processing. In adequately aerated and covered piles, temperatures of 1.5° to 5°C can be maintained even if the external temperature drops substantially below 0°C. If piles are not well prepared, microbial spoilage may follow damage to the beets, eg, after freezing or overheating (50°C), leading to the production of dextran, levans, or inverted sugars.[22,106] Postharvest losses can be minimized by optimal piling conditions or even by the use of controlled or modified atmosphere storage.[75,76,152] In the case of damaged beets, application of Benomyl® or thiabendazole prevented infection and spoilage by *Penicillium* spp. and *Botrytis* spp.[34] A simplified flow diagram of beet processing up to the raw beet sugar is given in Figure 35-2. Steps applied for the production of refined product are similar to the cane sugar in Figure 35-1.

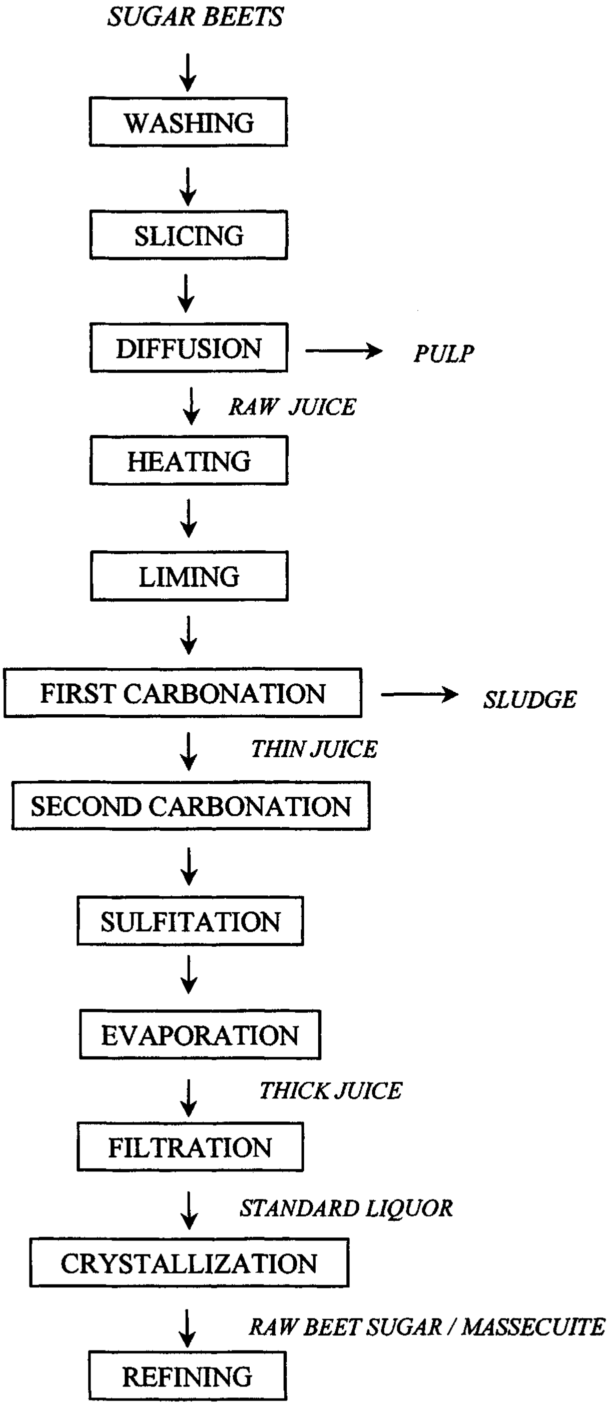

Figure 35-2 Flow Diagram of Beet Sugar Processing.

At the factory, the beets are flumed in water to washers at 30°–40°C. Residual soil is removed in the washers and microbial numbers can be reduced by either using fresh water or by chlorination of recirculated water.[18,96] Leaching of sugar and insufficient removal of some of the soil allow rapid microbial growth. In general the higher the levels of residual soil, the higher the contamination in the juice. Beets are then cut into cossettes or strips and sugar is extracted in diffusers using a counter-current of hot water, either in batch (older) or continuous processes. Diffusers are normally equipped with two ancillary systems, one for the extraction water and one for the juice, to pump, transport, filter, strain, heat, and store the liquids. Details of various beet processing lines are given by Salunkhe and Desai.[124]

Because of their way of operating, various gradients occur in diffusers and their ancillary systems, these include gradients of sucrose (0.5% to 1.5%), invert sugars, minerals, nitrogenous compounds, temperature (25° to 75°C), dissolved oxygen, or pH (5.0–8.0). Microorganisms originating from the beets will therefore be influenced by these ecosystems. The temperature gradient, for example, will favor growth of thermophilic forms between 65° to 70°C, and *Bacillus stearothermophilus* may reach levels of 10^6 to 10^7 ml^{-1} within a few hours[81] resulting in a pH decrease to 5.2 to 5.4.[107] Other thermophiles such as *Bacillus coagulans* occur, while *Clostridium* spp. have been detected in batch diffusers.[7,8,88] The water used for extraction is either fresh water or water recycled from the last extraction step, thus still containing recoverable sucrose (0.5% to 1%). Mesophilic or thermophilic microorganisms may be present, originating from pipes, strainers, filters, tanks, or from diffusion cells. Control can be exerted by heating the water to 80°C or higher, by the use of flocculants or by sanitizing systems with biocides.[14,42] During further processing, the raw juice is heated to 80° to 90°C and lime added in portions as aqueous suspension (milk) or as a slurry of calcium saccharates to precipitate colloidal material. Carbon dioxide is then bubbled through in two stages, the first to facilitate removal of sludge, the second to precipitate residual lime. Precipitates are removed by filtration, and the filtrate (thin juice) is treated with sulfur dioxide to lower the pH and destroy colors. The juice is then passed through ion exchangers, treated again with sulfur dioxide, sometimes filtered through kieselguhr prior to final evaporation (thick juice with a water activity of about 0.88), filtration (standard liquor), and crystallization.[113]

Microbial contamination or recontamination can occur at several steps during refining. Thermophiles are favored in the diluted product during deionization because of the relatively high temperatures. In the charcoal columns, both water activity and the temperature conditions preclude microbial growth, but elution of sugar prior to regeneration of the columns may allow development of thermophilic forms, such as *Clostridium thermosaccharolyticum*, that can produce slimes.[7] Sweet waters originating from bag washers, spillage, wash water from filters, charcoal, and ion-exchange columns may support growth of mesophilic and thermophilic organisms such as *Leuconostoc, Lactobacillus, Streptococcus,* and *Bacillus* spp. depending on nutrients or temperatures.[138,140]

Development of microorganisms, in particular of thermophiles, leads to destruction of sucrose and thus to losses, which may reach up to 1.3%[1] and are more marked in continuous systems.[80] Thus, growth of *B. stearothermophilus* and *B. coagulans*[89] will cause acidification of the juice, from 6.2–6.4 in the beet down to 5.2 to 5.4, mainly because of lactic acid, but also formic, acetic, and glycollic acid.[88,108] Gases such as carbon dioxide, hydrogen, or hydrogen sulfide may also be formed and will influence the extraction procedure.[81] Further effects of microbial growth are corrosion of the equipment, slime formation as a result of synthesis of dextran or levan from sucrose, and transformation of nitrate present in sugar beets to nitrite or nitrogen gas, the first having an impact on the ash content or eventually on the malformation of crystals. The situation concerning the development of fungi is similar to that outlined under Section 35.2.3 for cane sugar.

Liquid sugars are aqueous solutions containing 23% to 34% of water and different types have been developed to meet the needs of customers. They are obtained directly from refiners or, to save transport costs, from intermediate melting stations located near zones with an important number of users. In melting stations sugars are dissolved in water, solutions standardized, and then delivered. These products, however, are sensitive to spoilage and in particular to the development of osmophilic yeasts. Handling under highly hygienic or even aseptic conditions is therefore necessary, and equipment such as pipes, pumps, and tanks have to be designed accordingly. Tanks, for example, have to allow complete drainage and efficient cleaning and sanitation. In order to avoid condensation, ventilation systems that are equipped with absolute filters to remove microorganisms are needed. Normally, tanks are also fitted with UV lamps to sterilize the top, ie, headspace and surface of the tanks.[113]

Other Sugar Crops

In the case of different types of palms, sap is collected from the mechanically tenderized inflorescences or from slits made in the trunk. Microorganisms isolated from sap were identified as *Acetobacter aceti, A. rancens, A. suboxydans, Leuconostoc dextranicum, Micrococcus* spp., *Pediococcus* spp., and *Bacillus* spp., as well as yeasts such as *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe.*[127] Lime is added to prevent development of these organisms and fermentation of the sap. After precipitation of the calcium carbonate, the juice is strained and boiled to concentrate it. The syrup obtained is poured into molds for crystallization.[58] The heat treatment causes destruction of vegetative organisms, and the low a_w of the crystallizing syrup (about 0.80–0.83) inhibits growth of other organisms, such as spore-forming bacteria. Moisture uptake may occur in humid conditions and allow the development of molds.

Sweet sorghum (*Sorghum bicolor (L.)* Moench) is either harvested manually using cane knives or mechanically using machines such as corn binders or chopper harvesters. Elimination of leaves, seed heads, and peduncles allows the production of a syrup of higher quality.[23] Processing is similar to that of sugar cane and includes milling, clarification, concentration, cooking, and crystallization.[124] A problem with sorghum juice is the presence of up to 4% starch, which is gelatinized during concentration. Higher concentrations, however, will have adverse effects on the texture of the final syrup.

Dextrose, Fructose, Polyols, and Lactose

As outlined in the introduction, dextrose and fructose as well as the different polyols are derived from syrups, which are prepared as described in Section 35.3. Although not covered in specific publications, microbiological aspects related to the refining process from the syrups to dry crystalline powder are certainly comparable with those of sucrose. Lactose represents a particular case because it originates from milk or whey (45 to 52 g l^{-1}). Industrial lactose is extracted from concentrated whey or from whey permeate; the processing steps related to whey are described in the chapter on dairy products. Extraction of food grade lactose is summarized in Figure 35-3. Although references about this process are not readily available, microbiological problems related to the steps following crystallization are certainly similar to those of other types of sugar.

35.2.4 Pathogens and Spoilage Associations

Although *Clostridium botulinum* has been found in unrefined sugar,[103] this product generally has not been associated with pathogens and has thus never been linked to outbreaks of foodborne disease.

Granulated sugar is normally not a source of spoilage yeasts, unless problems such as moisture uptake cause increases in numbers.[100] Sugar may nevertheless represent a source of bacterial contamination, leading to spoilage of canned foods or bottled drinks. Stringent microbiological standards, in particular for mesophilic and thermophilic spores, have therefore been set by users such as bottlers and canners.[19] The following are examples of specifications.

Sugar for canning purposes:

Samples: 5

Total thermophilic spores: Average of not more than 125 spores in 10 g.

Flat-sour spores: Average of not more than 50 spores in 10 g.

Thermophilic anaerobic spores: May be present in up to three of the five samples, but in any one sample not more than four of six tubes inoculated by standard procedure should contain spores.

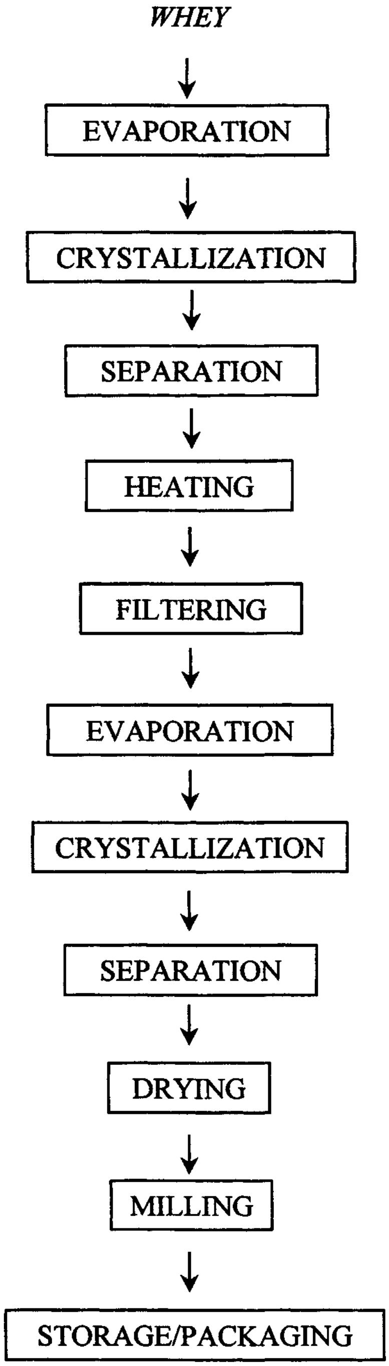

Figure 35-3 Flow Diagram of Lactose Production.

Sulfide spoilage spores: May be present in up to two of the five samples.

Sugar for bottling purposes:
Aerobic mesophilic bacteria: max. 200 cfu in 10 g.
Yeasts: max. 10 in 10 g.
Molds: max. 10 in 10 g.

In the case of liquid sugar for bottling purposes the same standards apply but they are expressed for 10 g of dry sugar equivalent (DSE).

35.2.5 Preservation and Prevention of Contamination

Methods of preventing recontamination, or multiplication during processing have been discussed under Section 35.2.3. The low water activity of granular sugar does not allow microbial growth, and inhibition is guaranteed as long as moisture uptake is prevented. In the case of liquid sugars, preventive measures applied in the frame of Good Manufacturing Practices (GMP) and Good Hygiene Practices are necessary to prevent contamination by and/or growth of osmophilic yeasts. Destruction can be achieved by sanitation and sterilization of the processing equipment and/or of the product, and recontamination during storage can be prevented by fitting tanks with air filters and UV lamps.[40,113] Prevention of condensation by ensuring proper aeration with filtered air is also important to avoid the generation of a_w gradients allowing multiplication of microorganisms in zones with increased a_w values.

35.3 SYRUPS

35.3.1 Composition

Sugar syrups have to fulfill requirements of the users in terms of concentration, composition and ratio of sugars (blends), technological properties, presence of additives.[12,79] They are manufactured for a wide variety of end users and products (eg, bakery, confectionery, drinks, jams, ice cream, meat products, clinical nutrition). These aspects are discussed in detail for glucose syrups by Jackson.[70] According to the Codex Standard 9-1981, glucose syrup should have a minimum of 70% total solids and of 20% dextrose equivalents.[21] Maple syrup is composed of sucrose (88% to 99%) and glucose and fructose (0% to 11%), has a dry matter of 66.5%, and contains several organic acids, minerals, and vitamins.[97]

35.3.2 Initial Microflora

Syrups are manufactured either from cane and beet sugar, from maple sap, or from starches of different origin such as potato, corn, or wheat applying acid or enzyme hydrolysis or a combination of both. The initial microflora of sugar cane and beets is discussed in Section 35.2.2.

Production of maple syrup and sugar is concentrated in the United States (US) and Canada. Sap is drawn from maple trees (*Acer saccharum* or *Acer rubrum*) each year from around mid-February to mid-April. Sap directly withdrawn from the tree is sterile. However, in the sap collected under usual conditions, yeasts and bacteria can be found. In their study, most bacteria were identified by Morselli and Feldheim[97] as *Pseudomonas fluorescens* and their presence was attributed to poorly sanitized collecting devices and tubes. Other studies have shown that the microbial flora of maple sap is related to that found on the trees and isolated from wood and the main organisms belong to the genera *Bacillus* and *Actinomyces*.[114]

Spoilage defects of sap collected under nonaseptic conditions have been described and green sap is due to the development of fluorescent pseudomonads, red sap to red yeasts and some bacteria, milky sap to bacilli, and ropy sap to *Enterobacter agglomerans* excreting exopolysaccharides.[15]

35.3.3 Effect of Processing

Invert syrup is manufactured from sucrose solutions ranging between 60% and 75% total solids, depending on the desired characteristics of the final product. Three techniques can be applied: enzymatic inversion using microbial invertase, acid inversion usually performed with HCl, and ion-exchange inversion on very acidic cationic exchange resins.[113] Most of these processes are carried out at temperatures between 65°C (enzymatic) and 90°C (acid). Starch is used as raw material for the manufacture of other types of syrups such as glucose, fructose, or maltose syrups, which in turn can be transformed into crystallized sugars. The most important types of starch are maize (corn in the US), wheat, potato, and tapioca.

Enzymatic degradation of native starch is very slow. Gelatinization and liquefaction of a starch slurry (30%–40% dry matter) at temperatures of 105° to 107°C are necessary to improve the enzymatic hydrolysis, which is then normally performed at lower temperatures (90° to 100°C) using thermophilic α-amylases of microbial origin.[109] The degree of starch degradation is expressed in dextrose equivalents (DE).

Partial hydrolysates, prepared either by acid or enzyme treatment, can be further treated by one or more enzymes to manufacture a wide range of products. High-maltose syrup is obtained by treating a converted starch slurry with β-amylase or pullulanase and high fructose syrup with an isomerase. High-glucose syrup is manufactured using amyloglucosidase and also serves as an intermediate to prepare high-fructose syrup. Maltodextrins are produced by stopping the conversion process at an early stage, while hydrogenation is used to prepare polyols from different sugar syrups.[82]

After conversion, syrups are filtered, decolorized, concentrated, and, if necessary, purified on ion exchange resins. Complete technical details on characteristics and manufacturing of starch hydrolysates are given by Blanchard and Katz[12] and Olsen.[109] Precise microbiological data on the manufacture of the different types of syrups are not easily accessible and the number of publications is very limited. Because of the conditions of processing no major change in microflora is likely to occur, except the destruction of vegetative organisms and of some spores. Depending on their sugar content and the type of sugar(s), syrups have water activities ranging between 0.70 and 0.85. They are therefore prone to spoilage by osmophilic yeasts such as *Zygosaccharomyces bailii* and *Z. rouxii*, which are able to grow at a_w values as low as 0.65.[142] Spore-forming bacteria may originate from the raw materials, starch being a possible source of thermophilic spore formers in canned foods.[63]

As in the case of liquid sugar, recontamination may occur during intermediate storage in tanks, and during transport in pipes, pumps, or trucks. The installation of absolute air filters and UV lamps as well as adherence to GMP are also recommended to prevent recontamination.[113]

Maple sap is an aqueous solution containing 1% to 9% sucrose,[97] which is concentrated to prepare maple syrup and sugar. Concentration is usually performed in special pans and syrup is then further transformed into hard and soft sugars in molds, the typical flavor and color being developed during heat processing. Normally 40 liters of sap are necessary to produce 1 liter of syrup. Details of preparation of different derivatives are given by Salunkhe and Desai.[124]

35.3.4 Pathogens and Spoilage Associations

The situation regarding pathogens is identical to that for sugars (Section 35.2.4) because this group of products has never been linked to outbreaks of foodborne disease.

The requirements for specifications regarding spore formers are similar to those outlined for sugars, in particular for syrups used in the bottling industry.[19] However, contrary to the situation in granulated sugars, the presence of osmophilic yeasts such as *Z. rouxii*, *Z. bailii*, or *Saccharomyces cerevisiae* is detrimental either to the syrup itself or for products manufactured using these syrups. Development in the product itself may lead to deterioration of organoleptic or textural characteristics, while contamination of confectionery products, for example, will cause fermentation, gas production, leakage, and product loss.[117]

The presence of *Clostridium botulinum* has been reported in 13 of 1,010 samples of corn syrup.[77] In the positive samples, levels of approximately 50 spores g^{-1} were found by MPN. The organism was not found in two further surveys, nor in 43 samples of several types of syrup[62] or 738 samples of corn syrup or products containing corn syrup.[85]

35.3.5 Preservation and Prevention of Contamination

Recontamination with osmophilic yeasts can be minimized or controlled applying the same measures as outlined under Section 35.2.5. In the case of the different types of sugar syrups, preventive measures applied in the framework of Good Manufacturing Practices and Good Hygiene Practices are necessary to prevent contamination by and/or growth of osmophilic yeasts. Prevention of condensation by ensuring proper aeration by filtered air is important to avoid generation of a_w gradients, allowing multiplication of microorganisms in pockets or surfaces with increased a_w values. In the case of maple syrup, destruction of microorganisms can be achieved by sterilization of the processing equipment or of the product, eg, before packaging.[37] Other techniques have been applied such as UV irradiation of surfaces of syrups during storage.[36,52]

35.4. HONEY

35.4.1 Composition

Honey is essentially composed of water (average 17%) and of the two sugars fructose (average 38%) and glucose (average 30%), other sugars including sucrose and maltose amounting to up to about 13%. Furthermore, organic acids, minerals, proteins, amino acids, and enzymes can be found. The composition of a honey sample will depend mainly on the type of nectar(s) and characteristic differences can therefore be observed. A compilation of the average composition of several types of honey is provided by White.[149] The water activity varies between 0.5 and 0.6 and the pH between 3.4 and 6.1 with an average of 3.9. The internationally accepted detailed norms are given in the Codex Standard 12-1981.[21] Different commercial forms are found, the traditional liquid or crystalline products or a mixture of both; solid crystallized or granulated honey resulting from glucose crystallization; the easily spreadable creamed honey obtained by a physical process. Comb honey and chunk honey are frequently seen, where combs are either commercialized as whole sealed pieces, sections of them, or as pieces added to liquid honey.

35.4.2 Initial Microflora

As outlined by Snowdon and Cliver[130] in their thorough review, microbes of interest to the honey processing industry are those able to withstand the specific characteristics of honey such as sugar, acidity, and presence of antimicrobials. The microbial content of honey is generally low and several surveys[130] have shown counts of <100 cfu g^{-1}, exceptionally of up to 1,000 or 10,000. *Bacillus* spp. have been identified as the dominant flora in most studies. The microorganisms found in hives come from the bee, the nectar, and pollen as well as from external sources. *Bacillus* spp. have been predominant isolates from feces of bee larvae[49] followed by Gram-variable pleomorphic bacteria, to a lesser extent by molds, *Actinomycetes*, Gram-negative rods and yeasts, whereas *Clostridium* spp. have not been found. This is in agreement with other studies on adult honey bees.[50,51] Because nectar is almost sterile,[48] it is suggested that pollen may be the main source of the intestinal flora. Secondary sources of microorganisms are humans, equipment, dust, insects, animals, water, and sweeteners. Comparison of microbial isolates from bees and honey[130] shows that certain intestinal organisms of the bee do not survive in honey. Vegetative bacteria, such as *Gluconobacter* spp. and *Lactobacillus* spp., present at initial stages, disappear during ripening of honey because of a drop of the water content to below 18%.[123] Two spore formers, *Bacillus larvae* and *Clostridium botulinum*, can be found at low frequencies in honey. The first is the cause of the "foul brood" disease of bees and has therefore an economic impact on honey production.[65] The isolation of *C. botulinum* from honey has been described by several authors[62,66,131] and has been related to outbreaks of infant botulism.[91] *C. botulinum* spores can survive for rather long periods in honey[104] and their increased incidence at higher levels seems to be linked to the presence of diseased bees in hives, favoring multiplication and sporulation.[102]

Molds are detected regularly in the intestinal content of bees and in the environment of hives. Molds are normally found in honey at low levels of 1 to 100 cfu g^{-1},[116] or 250 cfu g^{-1},[146] and widespread genera such as *Aspergillus* and *Penicillium* are usually found.[49,147] Xerophilic forms able to grow in honey have not been reported, suggesting that molds tend to survive but not to develop.

In the case of yeasts, *Saccharomyces* spp. are predominant[145] but other genera have been reported[130] including *Rhodotorula, Debaromyces, Hansenula, Lipomyces, Oosporidium, Pichia, Torulopsis, Trichosporon, Nematospora, Schizosaccharomyces, Schwanniomyces,* and *Zygosaccharomyces.* The concentration of yeasts is frequently proportional to the moisture content[27] and yeast counts ranging from 0 to 10^5 and even 10^6 g^{-1} have been reported.[55,122] Osmophilic yeasts, such as *Zygosaccharomyces,* found in honey, may originate from flowers and soil, other types from combs, air, and equipment.[122] *Z. rouxii* and *Z. bisporus* have frequently been isolated from honey[71,117] and high levels resulting from multiplication will obviously cause fermentation and lead to unacceptable organoleptic changes.

35.4.3 Effect of Processing

Heating is an essential factor in the processing of honey, but overheating must be avoided to minimize formation of undesired compounds such as hydroxymethylfurfuraldehyde (HMF) or color changes.[134] First, frames are stored at 32° to 35°C for about a day to improve extractability. With few exceptions, honey is extracted from decapped combs after removal of the wax layer covering the cells. Uncapping is performed either manually by means of a hand knife dipped into hot water, by electrically heated knives, or by automatic systems allowing several frames to be uncapped at the same time. Wax residues generated during this operation are separated by skimming, settling, or melting.

Extraction is performed by centrifugation, spinning the honey out of cells and then recovering the honey into sump tanks, which are often jacketed with warm water. Warming is then necessary to overcome cooling (through evaporation) that occurs during extraction, and heating to about 46°C in the sump tanks improves the subsequent settling and straining steps. The extracted honey is then strained using different types of strainers, from simple straining cloths to larger systems equipped with screens of different meshes. Before packing, honey is usually stored in bulk in tanks or drums and liquefied before repacking. Liquefying is normally performed in melting rooms heated by hot air (60° to 70°C).

The moisture content is a major parameter governing the keeping quality of honey. Honey is hygroscopic and may absorb considerable quantities of moisture if not stored under appropriate conditions. An optimum of 17% to 18% moisture can be maintained by controlling the environmental humidity at about 60%. Details on processing are given by Crane.[27]

35.4.4 Pathogens and Spoilage Association

The only pathogen of concern for public health is *C. botulinum,* which has been isolated from commercial samples (Section 35.4.2) (see Chapter 41). The occasional presence of Enterobacteriaceae is due to contamination during extraction and manipulation of honey.[17,116] As outlined under Section 35.4.2, osmophilic yeasts may cause spoilage at slightly increased water activities[126] or spoilage of confectionery products containing contaminated honey. Spoilage of honey by *Z. bailii* may occur at water activities ranging between 0.65 and 0.68.[143] Heat treatments at temperatures >60°C provide a killing effect despite the fact that the low water activity has a protective effect on the yeasts. Bacterial spores, however, will normally survive this treatment.

35.4.5 Preservation and Prevention of Contamination

Heating represents the only means of destroying osmophilic yeasts. Water activity is otherwise a good barrier and multiplication, in case of presence, can be inhibited by ensuring that it is kept at 0.65 or below, by avoiding moisture uptake (hygroscopicity, condensation). Postprocess contamination during handling of honey, originating from equipment or air in contact with the product, can be minimized or eliminated by applying Good Hygiene Practices.

Contamination by *C. botulinum* cannot be prevented and normal processing conditions are not designed to eliminate spores. Destruction can only be ensured by sterilization, preferably of diluted honey. Cases of infant botulism can be avoided by applying the recommendations issued by the American Academy of Pediatrics not to feed infants under 8 to 12 months old products with honey or products containing untreated honey (eg, water).

35.5 COCOA, CHOCOLATE, AND CONFECTIONERY

35.5.1 Composition

During processing of cocoa beans, several intermediate products are obtained that can be used to manufacture cocoa and chocolate products. Cocoa nibs are obtained from clean cocoa beans after mechanical breaking. Grinding of nibs allows production of a liquid cocoa mass, which can be separated under pressure into cocoa press cake and cocoa butter. Descriptions and detailed compositions of these intermediate products as well as others are given in the Codex Standards 86-1981, 105-1981, and 141-1983.[21]

Chocolate is a homogeneous product prepared from one or several ingredients mixed in different ratios, depending on the type of chocolate: cocoa butter (12% to 58%); cocoa solids (0% for unsweetened chocolate; otherwise 20% to 35%); milk fat (≅0.5% to 7%); fat-free milk solids (3 to >14%); and sugar (<55%). The precise definitions and composition of the different product categories are given in the Codex Standard 87-1981.[21]

In the literature and articles for laymen or consumers simpler descriptions may be found. "Milk chocolate" is composed of milk solids, milk fat, cocoa solids, cocoa butter, lecithin, and flavors as opposed to "dark chocolate," where the milk components are omitted and "white chocolate," which does not contain cocoa solids.

Confectionery products are very heterogeneous and will not be discussed here. Descriptions and definitions of certain products can be found in the Codex Standards 142-1983 and 147-1985.[21]

35.5.2 Initial Microflora of Cocoa Beans

The fruits of the cocoa, *Theobroma cacao* L., commonly referred to as pods, are removed from the trees by cutting the fruit stalk with a sharp instrument. Each pod contains about 30 to 50 beans (seeds) embedded in a sterile, acidic mucilaginous pulp (pH 3.6–4.0), rich in water and sugars.[10] The raw beans, composed of two cotyledons, a germ (radicle), and a seed coat (testa) contain about 30% water and 30% proteins, starch, sugars, phenolic, and other organic compounds.

The pulp and beans are contaminated during and after breaking of the pods by numerous external sources such as hands and tools of harvesters, earth, leaves, wood from containers, insects, and animals.[90,112] During fermentation, pulp residues are degraded by external microbial enzymes and internal enzymatic processes, leading to the synthesis of flavor precursors. Heat and acids formed during this phase also cause destruction of the germ, thus avoiding degradation of cocoa fat normally associated with germination.

The beans are allowed to ferment by applying very different techniques, depending on the region, and methods include fermentation in piles, heaps, baskets, wooden boxes, or trays.[128] Despite problems linked with the heterogeneity of the fermenting mass, changes resulting from mixing, and the different sampling methods applied, three different phases have been identified.[60,112] In most cases, succession of different microorganisms is not clear-cut and transition phases or overlaps occur.

Phase 1: During the first 1 to 2 days, yeasts form the predominant population. They metabolize sugars rapidly, in part to ethanol, and excrete pectinolytic enzymes, which break down the mucilaginous gel of the pulp. This facilitates draining of liquid from the pulp, the so-called sweating fluids. Subsequent catabolism of citric acid leads to an increase of the pH from 3.6–3.7 to 4.0.[45,125]

Phase 2: In the collapsed pulp, fermentative yeasts decline by the third day. During this phase, the low oxygen concentration or, if oxygen is present, the high carbon dioxide level, favor the development of lactic acid bacteria. Both homofermentative types, producing lactic acid as the main product, and heterofermentative ones, producing several products, with lactic acid making up 50% or more of the total, occur.[115] Aeration of the fermenting beans favors the development of acetic acid bacteria, which transform ethanol to acetic acid, which is, along with lactic acid, further oxidized to carbon dioxide. The oxidation gives rise to a temperature increase to 45° to 50°C.

Phase 3: These conditions and the steadily increasing pH favor the development of thermophilic spore-forming bacilli. Tetramethylpyrazine, an important component of cocoa flavor, is synthesized by *Bacillus subtilis*.[111,155]

The microflora of fermented beans is representative of the microorganisms of the successive populations and is composed of yeasts, acetic acid and lactic acid bacteria, and *Bacillus* spp., as well as contaminants or spoilage organisms originating from the environment.[112] Spoilage of fermenting beans because of the development of *Aerobacter* spp. and *Pseudomonas* spp. has been observed at pH values above 5.0. Molds may grow on the outer surfaces of beans if regular mixing is not ensured.[121] Penetration of the beans, in particular by *Aspergillus niger, Aspergillus flavus, Penicillium* spp., and *Mucor* spp., however, may occur if sufficient oxygen is available, causing changes in the fatty acid profiles.[59,61] The presence of mycotoxins has, however, only rarely been reported in cocoa.[83] This is probably due to elimination of shells during further processing or to the inhibiting effect of caffeine in beans, where it may be present at concentrations of 0.3 to 3.6 mg g^{-1} depending on their origin.[84,153]

Fermented beans are then dried, either artificially or naturally, to reduce the water content to 6% to 8%. The microflora of dried beans is composed mainly of mesophilic and thermophilic spore formers, followed by vegetative organisms, such as *Enterobacter* spp., *Flavobacterium* spp., and *Micrococcus* spp. as well as yeasts and molds.[5,60]

Subsequent handling, transport, and storage of dried beans may lead to spoilage by xerophilic molds in the case of damaged or improperly dried beans (moisture uptake above 8%).[60] Mold growth is often linked with the occurrence of off-flavors because of lipolytic activity or the excretion of metabolites dissolving in the fat phase.[61,78]

35.5.3 Effect of Processing

A very general flow diagram of chocolate processing is given in Figure 35-4. Numerous alternatives may exist, depending on the manufacturer. The vast majority of microorganisms are found on the outer surface of undamaged beans. Considering their origin and the way in which raw and fermented beans are handled, the presence of *Salmonella* is also likely. Roasting represents the only processing step allowing destruction of the pathogen. The heat treatments are also essential steps in the development of chocolate flavor, initiating important chemical reactions.[154]

Before roasting, raw fermented beans are cleaned to remove extraneous materials. Different roasting processes have been developed including roasting of whole beans, of nibs obtained by breaking beans in winnowing machines, or of cocoa liquor obtained by passing cocoa nibs through grinders and refiners.[87] Temperatures applied during roasting depend very much on the type of cocoa processed and the organoleptical profile desired by the manufacturer. Initial moderate temperatures eliminate excessive water and distribute moisture evenly in the beans, temperatures ranging between 100° and more than 200°C can be applied at later stages. Temperatures of about 105° to 150°C are sufficiently high to destroy vegetative microorganisms, including pathogens

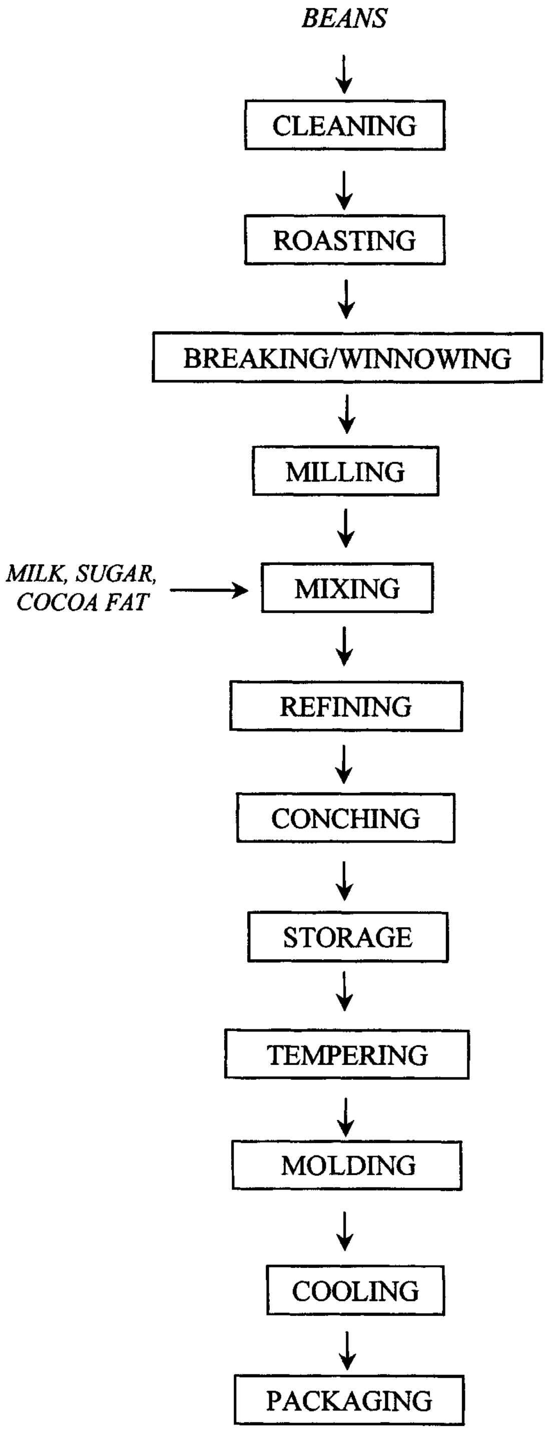

Figure 35-4 Flow Diagram of Chocolate Production.

such as salmonellae. Other processes, such as infrared heating or steam treatment designed to enhance separation of shells from beans and to minimize fat losses, may even allow destruction of spores.[95] However, the most important reduction is normally achieved through elimination of shells during winnowing.[86,92] As can be expected, the microflora of roasted beans is composed of spores, and species such as *Bacillus stearothermophilus, B. licheniformis, B. subtilis, B. coagulans, B. circulans, B. brevis*, and *B. megaterium* have been reported.[5,112]

For the production of chocolate, roasted beans, nibs, or liquor are submitted to several processing steps: milling and refining to obtain the desired granulometry; mixing to blend the cocoa mass evenly with ingredients such as milk powder, sugar, and cocoa butter; conching to agitate the chocolate mass in order to achieve the required degree of plasticity and allow for flavor development; tempering during which the fluid chocolate is submitted to temperature cycles to favor correct fat crystallization; and finally molding.[94] These steps have no major effect on the original flora as shown by analysis of finished products.[25] The levels of microorganisms depend on the initial flora and the roasting conditions applied. Minor changes in the species found may be influenced by added milk powder, sugar, or other ingredients, such as nuts or dry fruits added before molding. The presence of heat-sensitive microorganisms, including indicator organisms or salmonellae, is indicative of postprocess recontamination from added ingredients or from the environment.

In the case of cocoa powder, either nibs, cocoa liquor, cocoa powder, or press cake is exposed to alkali and temperatures of 85° to 115°C (alkalinization or dutching). The physicochemical changes in flavor and color achieved under these conditions are summarized by Minifie[94] and bactericidal effects also occur. Contamination by microorganisms such as spore formers[43,99] during the subsequent processing steps (pressing to extract cocoa butter, breaking of the press cakes, grinding of the kibbles, cooling, and packaging of the powder) is normally due to dust from the environment and can be minimized by protecting the product.[94] The heat generated during grinding may lead to condensation and thus to the development of molds in ducts and conveyors if no appropriate measures are taken to dry cooling air.[94] Viable counts in excess of 10^4 cfu g^{-1} indicate poor manufacturing practices.[24,90]

A very wide range of products is included in the categories chocolate confectioneries and sugar confectioneries, ie, bars, blocks and bonbons, boiled sweets, toffees, fudge, fondants, jellies, pastilles, and many others including very regional or local products. Manufacturing processes for several of these products are described by Minifie.[94] Processing conditions, in particular heat treatments, may vary greatly depending on the characteristics of the product manufactured. Treatments may range from very mild warming with limited killing effect to very effective cooking or boiling achieving complete destruction of vegetative organisms.[129]

35.5.4 Pathogens and Spoilage Associations

Although survival of *Staphylococcus aureus* in chocolate has been described, growth is not possible and therefore enterotoxin synthesis can be excluded.[110] *Salmonella* is the only bacterium that has caused outbreaks of disease associated with cocoa or chocolate.[29,68] Several episodes of salmonellosis have occurred over the last 20 to 25 years (summarized in Table 35-1). Some of these outbreaks have had an important economic impact, in some cases causing collapse of the companies involved.[120,141] A recent survey of chocolate in Mexico has shown that the problem is still of concern, even if no further outbreaks have been reported.[144]

In the case of chocolate, infections are due to the conjunction of very particular conditions. *Salmonella* has been shown to survive over very extended periods of time, even years in naturally contaminated products.[119,132,133] The pathogen also shows a strongly increased heat resistance because of the low water activity of chocolate and the protective effect of fat. Temperatures of 70°–80°C reached during milling, refining, or conching and even after overheating at >100°C were not sufficient to destroy small numbers of *Salmonella*.[53,54,119] A killing effect at around 70°C was achieved in some trials only after addition of 2% of water.[4] Application of this procedure in practice would, however, require proper validation as recommended by the IOCCC.[68]

In several of the outbreaks associated with chocolate, low levels of contamination have been reported (Table 35-1). On the basis of the quantity of product consumed or the fraction of the product contaminated (eg, only in the case of confectionery), very low infective doses, ≅10 to a maximum of 100 salmonellae, have been estimated. These remarkably low infective doses may be explained by the short intragastric residence of chocolate and the protective effect of fat allowing pathogens to enter the intestinal tract.[29,133] Chocolate and confectionery products do not support growth of pathogens. However, if contamination with *Salmonella* occurs, then the pathogen can survive for prolonged periods of time.[32,46,54]

Chocolate is characterized by very low water activities ranging between 0.4 and 0.5[118] thus impeding any spoilage. One single publication representing a special situation dealt with spoilage of chocolate containing different types of sweeteners and with varying equilibrium relative humidities (32% to 45%).[105] In this case, growth of molds at the interface between chocolate and packaging material has been attributed to the hygroscopicity of the sweeteners.

For cocoa powder, formation of off-flavors by molds metabolizing trichloranisol present in packaging material has been described.[150] Development of molds, however, is only possible if conditions are favorable as in the case of moisture uptake.

Spoilage of confectionery products depends very much on the water activity of individual products or product groups. The lower the water activity the more stable the product.[118] Thus, hard candy (a_w 0.2 to 0.35) is hardly affected, while jellies, marshmallow, or fondant (a_w 0.60 to 0.70) may suffer from spoilage due to osmophilic yeasts or xerophilic molds. Growth of fungi leads to visual deterioration of products such as marzipan, syrups, jams, candied fruits, confectionery, etc, by gas formation, fractures or bursting, formation of slime, color changes, development of off-odors and off-flavors, and enzymatic liquefaction.[13,20,71,93,98,143,151]

Table 35-1 *Salmonella* Outbreaks Linked with Chocolate Products

Year	*Outbreak*	*Serotype*	*Number of Cases*	*Level of Contamination [cfu g^{-1}]*	*Product*	*Origin of Contamination*	*Reference*
1970	Sweden	*S. durham*	110	?	Confectionery	Cocoa powder	44
1973	US/Canada	*S. eastbourne*	200	0.2–1.0	Candy	Environment	28, 30, 31
1982/1983	UK	*S. napoli*	245	2–24	Chocolate bars	Water	47, 56
1986	Canada	*S. nima*	29	0.005–0.025	Chocolate coins	Cross-contamination (?)	64
1986	Norway/Finland	*S. typhimurium*	>300	?	Chocolate	Birds	72, 73, 74

35.5.5 Preservation and Prevention of Contamination

The stability of chocolate is ensured by its low water activity, preventing development of spore formers as well as of contaminating organisms, including *Salmonella*. Thus, no further preservatives are required and safety of the products must be ensured by the application of appropriate preventive measures throughout manufacturing.

As mentioned above, roasting or alkalinization represents the only processing steps allowing destruction of *Salmonella* (critical control point, CCP). Because no further operation during production of cocoa powder, chocolate, and part of the confectionery products allows the destruction of vegetative organisms, recontamination with the pathogen must therefore be avoided by the introduction of appropriate measures based on the Hazard Analysis Critical Control Points (HACCP).

This starts at the level of the raw materials. Raw materials of agricultural origin such as raw milk, raw nuts, or raw fermented beans are not CCPs and control must be exercised by carefully monitored heat treatments. Processed raw materials can be subdivided into high risk (eg, gelatine, starch, egg products, dairy products) and low risk (eg, sugar, cereals) and preventive measures adapted accordingly. Preventive tools range from the careful choice of suppliers, the performance of audits, the verification by means of analyses for *Salmonella* and for indicators, such as coliforms, and examination of recorded monitoring data. Rework plays an important role in the chocolate/confectionery industry, and it should be handled as high-risk raw material. Further raw materials to consider are water, used in large quantities in jacketed systems, and air, which may be introduced directly into the product.

In processing plants, particular attention must be paid to the layout of buildings, premises, equipment, and personnel movements to allow for an optimal segregation between clean and unclean, and wet and dry zones. Extensive discussions on HACCP for cocoa, chocolate, and confectionery products can be found in different publications.[26,67,68] Guidelines of Good Manufacturing Practices (GMP) for the same group of products have been issued by the IOCCC.[69]

The several outbreaks presented in Table 35-1 underline the failure of preventive measures and were attributed to contaminated raw materials in the *Salmonella durham* outbreak,[44] inadequate layout and cross-contamination in the *S. eastbourne* outbreak,[28] probable contaminated water in the *S. napoli* case,[47] and probable cross-contamination through birds in the most recent *S. typhimurium* outbreak.[73,74] For the cocoa powder also, no additional preservatives are necessary, the low water activity being sufficient to guarantee stability.

In the case of confectionery products, preservation is ensured using different hurdles depending on the characteristics of the products, these hurdles include heat treatments, low water activities, or organic acids (acidulants). Contamination and development of spoilage fungi introduced with ingredients such as flours or starches, sugars or syrups, nuts, dried fruits, or jams or from the environment and air can be minimized or avoided by preventive measures, strict adherence to hygiene and good manufacturing practices and maintenance of the effective hurdle. Failures may lead to contamination and subsequent spoilage by osmophilic yeasts or xerophilic molds.[35,148]

36.1 INTRODUCTION

The products in this chapter have in common that they are prepared with boiling water and consumed as a drink. They are products of long standing of which tea appears to be the oldest, with a history of 2,000 years.[93] In the Western world, tea and coffee drinking became a habit about 300 years ago but herbal infusions have been used as a beverage and for medicinal purposes since the Middle Ages. The world annual production of tea is 3 million tons and that of coffee nearly 6 million tons; herbal teas form only a small fraction of the coffee and tea market.

36.2 TEA

36.2.1 Composition

Tea is produced in the tropical and subtropical regions of the world from the tea plant *Camellia sinensis*.[8] The plant is grown as a bush at high elevations (typically 500–2,000 m); the young top leaves of the bush are plucked and used for making black or green tea. The basic difference between these teas is the way the leaves are processed. Green tea is unfermented and the leaves are "fired" directly after picking to inactivate the leaf enzymes that would otherwise initiate oxidative fermentation. Black tea is made by initiating an enzymic oxidative fermentation process between picking and "firing." The fermentation of the leaf is caused by enzymes released from the tea after withering (moisture loss) and maceration. Enzyme activity is stopped by the drying process ("firing") thereafter. A third type of tea (oolong) is a semifermented tea that is allowed to ferment for a short period only. Black tea forms *ca.* 75% of the total volume of tea produced with *ca.* 25% being green tea. Much of the green tea is consumed in China and Japan and is not exported.

Black tea is defined according to International Standards Organization (ISO) 3720 as "Tea derived solely and exclusively, and produced by acceptable processes, notably fermentation and drying, from leaves, buds and tender stems of varieties of the species *Camellia sinensis* (Linneaus) O. Kuntze, known to be suitable for making tea for consumption as a beverage."[42] According to this standard, tea must have no taint and must be reasonably free from extraneous matter. Other chemical requirements are set to prevent the adulteration of tea with minerals, the sale of spent leaf, and to ensure the adoption of good plucking and sorting standards (a minimum of 32% water-extractable solids, a maximum of 16.5% crude fiber, a maximum of 1% acid-insoluble ash, and a total ash requirement of 4% to 8%). The moisture content, which may be determined by drying at 103°C, is not specified in the ISO standard, although it is the low moisture of the final product that ensures the long storage life of tea. In practice, the moisture content of high-grown black tea may range from 3% to 4% directly after drying, to about 7% to 8% after shipment to the tea packing plant. Low-grown tea (cultivated below 500 m altitude) is exposed to more humid conditions than tea grown at higher altitude and may have moisture levels close to 10% (see Section 36.2.3). For green, artisanal tea this may be above 10%.

The main characterizing components of tea are its polyphenols, often incorrectly referred to as tannins. The main polyphenols of green tea (the colorless catechins) are converted during the fermentation step of black tea production into the red-brown theaflavins and thearubigins. The polyphenols of black tea constitute 10% to 20% of its dry weight, and *ca.* 30% of the solids extracted during brewing of the tea to prepare as a beverage. The other important characterizing component of tea is caffeine, which constitutes 1.5% to 5% of its dry weight and 5% to 8% of the solids extracted during brewing.

36.2.2 Initial Microflora

Little has been reported about the microbial load of fresh tea leaves. Analysis of fresh leaves of the Yabutika cultivar, commonly used for green tea production in Japan, established a mold and yeast count of 7,500 g^{-1} of which *ca.* 2,500 g^{-1} was tentatively identified as *Cladosporium cladosporoides*.[15] Fresh leaves from gardens near Bangalore (India) were analyzed (after frozen storage) on three separate occasions (in March, May, and July). The counts obtained varied from 14,000 g^{-1} (May) to 193,000 g^{-1} (July), with an intermediate count of 82,000 g^{-1} in March. Mold counts ranged from 45 g^{-1} in July to 600 g^{-1} in March. Yeasts were not detected ($<10\ g^{-1}$).[53]

36.2.3 Effect of Processing

Green Tea (Unfermented)

In Japan, tea is plucked for steamed, green tea over three seasons of the year. The plucked leaves are first steamed for 45 to 60 seconds to inactivate the leaf enzymes, and then curled and dried in hot air at 90°–100°C for 40 to 45 minutes. During this first drying step, the moisture content is reduced from 76% to *ca.* 50%. This is followed by two successive drying and rolling steps, which are concluded with a final drying process at 80°C, to a moisture content of 6%. Pan-fried Chinese green tea is manufactured by firing fresh leaves in a pan at 250°–300°C for 10 to 15 minutes with frequent agitation to prevent burning of the leaves. The leaves are finally rolled and dried at 100°–150°C in a pan.[81] The steaming or pan-firing of the leaves will not only inactivate enzymes, but may also kill most microorganisms and result in a low count. This is in line with a mold count of 250 g^{-1} for a sample of Japanese green tea and of 750 g^{-1} for a sample of 100-year-old green tea.[15]

Oolong Tea (Semifermented)

Fresh tea shoots are withered (to reduce moisture content) under sunlight for 30 to 60 minutes, followed by 6 to 8 hours indoor withering on a floor, with gentle hand rolling and agitation. The moisture content is reduced from 78% to 60% during this operation. After this controlled withering process, the leaves are "fired" in a pan at 250° to 300°C for 15 minutes to stop the fermentation. This is followed by further rolling and drying as for the pan-fired green tea.[81] As noted for green tea, the pan-firing will inactivate most microorganisms and the dry tea will have a low microbial load as a result. A mold count of 50 g^{-1} was obtained for a sample of oolong tea.[15]

Black Tea (Fermented)

Black tea manufacture comprises essentially five steps.[35] These are: (1) partial removal of moisture from leaves (withering); (2) leaf disintegration into small pieces (cutting, rolling); (3) quality development by exposure to air (oxidation or fermentation); (4) completion of moisture removal (drying or firing); and (5) sieving into size fractions with fiber removal (sorting). Step two is done by (i) the orthodox process, (ii) the CTC process (crush, tear, curl), or (iii) the LTP process (Lawrie Tea Processor).[35,92]

Withering results in a significant increase in bacterial count (by a factor of 5 to 50). For instance, counts were 0.5 to 2 million after withering of the previously mentioned Indian teas (Section 36.2.2); the mold counts remained relatively low (1,000 to 10,000 g^{-1}) and only a few yeasts were found.[53] Following the rolling and cutting process, there was little change in counts.

During fermentation, cytoplasmic polyphenol oxidase reacts with the polyphenols from the disrupted cell vacuole. The latter process produces heat with the uptake of oxygen and the fermentation results in the formation of the pigmented, water-soluble polyphenolic compounds typical of black tea.[71] The fermentation may take between 40 minutes and 3 hours depending on temperature and process used. Traditionally, the fermentation took place in a thin layer of tea leaves on the floor, which ensured adequate air supply, and good cooling of the leaves, as fermentation is best carried out at 30°C. This was followed by fan-assisted deep layer fermentation in which air was blown through tea leaves via a perforated floor. In modern continuous fermentation, the "deep bed nonperforated system," the tea leaves are held in a large installation in thick layers, which are regularly exposed to air, to provide a hygienic and temperature-controlled fermentation during which the leaf temperature can be well controlled.[35] The main result of the fermentation is the production of the theaflavins and thearubigins that characterize black tea. During fermentation, the bacterial counts increased slightly to 1 to 10 million in the Indian teas studied by Marthi[53]; the mold counts remained unchanged (*ca.* 1,000 g^{-1}) but the yeasts started to grow reaching levels of 50,000 to 500,000 g^{-1}. In another study[69] bacterial and fungal counts apparently decreased slightly (by a factor of 2 to 3) during the first hour of fermentation but this may be within the statistical variation of the analytical method. As with the production of any food product, proper control of hygiene, and in particular the cleaning/sanitation of the equipment and surfaces in contact with the tea, is important to prevent the build-up of high concentrations of microorganisms, leading to taints and other undesirable quality defects.[69,92]

The microbial flora may also contribute to the fermentation process by their polyphenol oxidase and peroxidase activity. Out of 10 bacterial isolates from tea, 8 showed polyphenol oxidase activity, the most active being three *Bacillus* spp., which also showed peroxidase activity.[68]

The microbial load is significantly reduced during firing. The rate and amount of inactivation depend on the profile of the dryer. The temperature of the leaf during drying is not equivalent to the temperature of the dryer because of evaporative cooling of the material being dried. In trials in India, tea fired at a temperature of 135°C resulted in a maximum leaf temperature of *ca.* 90°C. This would be expected to give a significant decrease in count but this was not always observed. Thus, two samples of "fired" tea had counts of 5,000 and 20,000 g^{-1}, whereas a further sample had a count of 6 million g^{-1}. Mold counts were low (55 g^{-1} to 3,550 g^{-1}) and yeast counts varied from 3,000 to 40,000 g^{-1}.[53] The high temperatures are only reached at the end of the firing process, at a time when the heat resistance of surviving microorganisms will be increased because of the low water activity of the leaf at the end of the drying process. In countries with high humidity (low-grown teas), air drying is intrinsically more difficult and teas tend to have moisture contents above the target of 3% to 4%, although also drier design factors (overloading, delays in packing, inadequate capacity) may be a contributor.

After the main processing steps, the tea is graded and sorted. During this sorting operation, it is important that humidity is controlled as dried tea easily takes up moisture from the surrounding air.[35,92] After grading, the tea is bulk packed for transportation to the tea auction. Traditionally, wooden chests were used, but nowadays most fannings, dust, and broken grades of tea are packed in multiply Kraft paper sacks with a polyethylene/aluminium barrier liner that better protects the tea from the ingress of moisture.

From the auction, the tea is transported to the tea packing plant, where the tea is unpacked, sieved to eliminate stalks and other foreign bodies, and then blended in large rotating drums to produce the tea quality required by the customer. At this point in the production chain, black tea will have a typical moisture content of 4% to 7% (maximum, 10%).

Decaffeinated Tea

The caffeine present in tea can be extracted by methylene chloride, ethyl acetate, or super-critical carbon dioxide. As caffeine inhibits aflatoxin formation (Section 36.4.3), its removal may make decaffeinated tea more likely to support aflatoxin production should it become wet and moldy.

Instant Tea

About 1% of tea is transformed into instant tea. The tea raw material may be black tea (fermented undried leaf) or oolong or green tea. The tea is extracted with water at temperatures from 15°–100°C in a batch or continuous process. The yield of soluble solids is *ca.* 25% to 35% of the weight of the dry leaf. The tea extract or liquor is normally treated with additional processes before it is concentrated and dried.[74]

Concentration of the tea liquor is by evaporation, reverse osmosis, or freeze concentration until a liquor is produced with a solids content of *ca.* 35%. The final step in the process is spray drying the liquor. Vanos et al.[91] studied the microorganisms present at different points in the instant tea production process, as well as the effect of tea components on pathogens and spoilage microorganisms. Lactic acid bacteria were predominantly present, with *Lactobacillus plantarum* the major species. To prevent the growth of lactobacilli, the process line should be kept at <10°C or >50°C. The pathogens studied were unable to grow in the tea liquor.

36.2.4 Spoilage Associations and Pathogen Hazards

Spoilage

Tea processing includes a number of steps where microbial numbers may increase or decrease as described previously. The initial drying to 3% to 4% moisture ensures that no microbial growth can occur in the dried black tea. Such tea will take up moisture from the environment to give a moisture content of 5% to 7%; the moisture content of green teas and low-grown black tea may increase more to 10% to 11%. This will not, however, result in spoilage as moisture levels close to 15% are required for spoilage to occur. With respect to spoilage, the concern is mainly the possible growth of molds, when tea becomes sufficiently wet to reach a water activity of 0.7. This may occur during transportation and storage and is normally visible as a recognized defect. Tea chests and sacks containing moldy tea should not be used.

Pathogen Hazards

There is no substantial evidence for mycotoxin formation in moldy tea except for a report of the finding of 2.8 to 18.4 µg aflatoxin B_1 and B_2 kg^{-1} in four samples of Egyptian tea powder, heavily contaminated with *Aspergillus flavus* and *A. parasiticus*[1]; the tea when tested had a normal moisture content of 5.8 to 8.1%. When wetted and inoculated with *A. flavus*, 72 µg aflatoxin B_1 and B_2 kg^{-1} were produced after 2 weeks storage at 28°C followed by 2 weeks at 15°C.

The European Union's Scientific Committee on Food recently reviewed the microbiological risks associated with tea and concluded that: "Tea has a long history of safe use and the Committee is unaware of any safety problems related to moisture in tea. This may be attributed to its low moisture content (ie, water activity) and the high content of antimicrobial substances. Moisture levels up to 10% seem to give an acceptable safety margin for the storage of tea. A lower level may be needed to restrict quality defects."[77]

36.2.5 Antimicrobial Activity

Laboratory tests have demonstrated that tea has significant antimicrobial properties. Thus, Ryu demonstrated that 0.5% tea powder inhibited *Staphylococcus aureus, Vibrio cholerae, Salmonella typhi,* and *S. paratyphi* but that *Escherichia coli* was only slightly inhibited; a 3% suspension killed *V. cholerae,* with an initial concentration of *ca.* 100 to 1,000 bacteria ml^{-1}, in 30 minutes.[72] Further studies with 1% oolong tea powder extended inhibition by tea to *S. typhimurium, Proteus mirabilis,* and *Pseudomonas aeruginosa; Klebsiella pneumonia* was resistant.[73] Ryu hypothesized that tea tannins may be responsible for the antimicrobial activity, and it was later confirmed that tea polyphenols (catechins and theaflavin) were responsible for growth inhibition of *Clostridium botulinum* and a number of other Gram-positive and Gram-negative pathogens including *Vibrio parahaemolyticus, V. fluvialis, V. metchnikovii, S. aureus,* and *C. perfringens.*[36,37] The latter study found no activity of tea polyphenols against *E. coli, Yersinia enterocolitica* or *Campylobacter jejuni,* and *C. coli.* There are thus significant differences in the sensitivity of bacterial species to inhibition by tea and tea extracts. A strong decoction of tea (25 to 30 g in 150 ml water) is often used as therapy in India during an episode of diarrhea,[78] whereas Japanese green tea is bactericidal to a number of pathogens at a concentration of tea used in daily life.[88] A recent mini-review gave a comprehensive literature survey of the antimicrobial properties of tea.[34]

36.2.6 Preservation

There are few published data on the microbial flora of packed teas. Zhao et al.[96] analyzed 25 samples of leaf tea for coliforms and fecal coliforms and reported that the numbers of coliforms and fecal coliforms were <10 g^{-1} in 32% of the samples, between 10 and 100 g^{-1} in 60% of the samples, and above 100 (maximum 1,100) in 8%. Data recently collected from a few tea packing stations in India are shown in Table 36-1.[14] These data represent only tea from a limited source and may not be representative of different teas from different sources. For instance, green tea from China may have up to 10 times higher counts because of the more artisanal firing process applied. Spain is one of the few countries with mi-

Table 36-1 Aerobic Plate Count, Yeasts/Molds and Coliforms of Indian Retail Black Tea ($n = 182$)

Counts g^{-1}	*0–*10^3	*>*10^3*–*10^4	*>*10^4*–*10^5	
Aerobic plate count	28%	65%	7%	
Yeasts and molds	45%	53%	2%	
Counts g^{-1}	*0–10*	*>10–*10^2	*>*10^2*–*10^3	*>*10^3
Coliforms	65%	18%	14%	3%

crobiological limits for tea: aerobic plate count max. 1 million g^{-1}, *Bacillus cereus* max. 10^3 g^{-1}, *E. coli* max. 10 g^{-1}, molds max. 10^4 g^{-1}, and absence of *Salmonella/Shigella* in 25 g.[4]

The excellent preservation status of dried tea comes to an end when tea is infused with boiling water to prepare a cup of tea. When tea is consumed hot, there will be no microbial problems. In fact the normal brewing of tea will inactivate the few non–spore-forming organisms present and a perfectly safe drink will result. This holds also for iced tea, when first a hot tea is prepared with boiling water and the drink is chilled thereafter with ice cubes or in a refrigerator.

However, under abuse preparation and holding conditions, bacterial growth may take place in brewed and iced tea. There have been instructions on the label of packed black tea in the United States (US) to prepare iced tea with cold water by brewing the tea in the refrigerator for a few hours. Such instructions can lead to contamination with coliforms and other organisms present in tea. Claimed high levels of fecal coliforms in iced tea drinks have caused concern to the authorities in the US and comment in the media. However, these so-called "fecal coliforms" were in fact *Klebsiella* and *Enterobacter* species, organisms that are common in tea; in fact no *E. coli* was present.[24] It has been pointed out that species of *Klebsiella* and *Enterobacter* are commonly associated with plants and plant materials, where they do not represent fecal contamination. The "fecal coliform" levels in iced tea samples from restaurants in the US varied from 15 ml^{-1} to 1,100 ml^{-1} and high numbers were the result of poor hygienic practices in the preparation and storage of the iced tea.[96]

It is not recommended that tea be prepared by brewing in the sun (sun tea) as is suggested on the label of some teas sold in America. Sun brewing for a few hours will result in temperatures that are ideal for microbial growth, and organisms such as coliforms, that will often be present in low numbers, will start to grow and reach numbers that are no longer in line with good hygienic practice. It is therefore recommended that proper instructions (text or pictogram) are given on packs of dried tea to use boiling water to prepare a tea drink and to use water over 85°C for tea in vending machines. After water, tea is the most common drink in the world. Tea is also probably the safest beverage in the world.

36.3 HERBAL TEAS

36.3.1 Composition

Herbal teas are not, formally speaking, teas as they are not made from *Camellia sinensis;* they are often referred to as herbal infusions or as infusions.[94] They are the dried aromatic parts of plants consisting of root, root-stock, shoots, leaves, flowers, barks, fruits, or seeds, which after preparation with boiling water are suitable as a drink. A few examples are chamomile (flower), mint (leaf), licorice (root), rosehip (seed), and apple (fruit). A list of over several hundred herbal teas and drugs is given by Hörhammer[41] but the number used commercially for herbal tea production is well below 50.

Herbal tea raw materials are cultivated in many countries of the world as they are grown where climatic conditions are most suitable for particular plants. Thus, chamomile is grown in Italy and Latin America, hibiscus in Morocco, rooibos in South Africa, and mint in many European and African countries. Some of these, such as mint, are harvested as moist materials and dried thereafter, while others, such as chamomile flowers, are dry when collected.

36.3.2 Initial Microflora

Few studies have been done of the microbial flora of herbal tea materials in the field. The flora on lavender (*Lavandula angustifolia*) and nine leaf plants growing in a garden in the University of Messina (Italy) was investigated.[2] The lavender flowers had an aerobic plate count (APC) of *ca.* 2.5 million g^{-1} (comprising mainly yeasts) whereas the leaf materials had lower counts of 10^4 g^{-1} to 5×10^5 g^{-1} and comprised variable numbers of Gram-negative and spore-forming bacteria. Chamomile and peppermint grown by three French growers were analyzed.[10] The average APCs on fresh materials from each of the three growers of chamomile were 2.5×10^5 g^{-1}, 2.9×10^6 g^{-1}, and 1.0×10^8 g^{-1}, ie, there was nearly a thousand-fold difference in microbial numbers on chamomile samples from the three growers. Numbers of yeasts and molds on the fresh chamomile were 10^4 to 10^5 g^{-1}. Bacterial groups present included fecal streptococci, pseudomonads, Enterobacteriaceae, and sulfite-reducing clostridia. The APC results for the fresh peppermint showed similar large differences in the levels of microbial contamination on materials from different growers.

36.3.3 Effect of Processing

Little has been published on the effects of processing (mainly drying) on the microbiology of herbal tea raw materials. However, it is apparent that the initial microbial load will be high and the types of microorganisms, as would be expected on any raw plant material, will be very variable. Mild conditions are used for drying to avoid loss of flavor, color, or essential oils, and such conditions do not have a marked effect on the microbial flora.[2,10,56] For balmmint, the dried material had counts of *ca.* 10^5 g^{-1}, quite similar to the fresh and semiprocessed raw material.[76]

The production of rooibos tea, prepared from an indigenous South African shrub (*Asphalathus linearis*) is different from that of other herbal teas because it is the only one that is fermented. Young green twigs with needle-like leaves are collected from plantations, transported in bundles to processing farms where they are cut into pieces of *ca.* 5 mm in length. Water is added, and the twigs are bruised and put into heaps to ferment for 8 to 24 hours at about 30°C (24° to 38°C). During the fermentation, chemical changes take place as a result of the enzymes released from the leaves and their color turns to amber-red. Microbial numbers increase during the fermentation and prefermentation handling stages. For example, in one study coliform bacteria increased from 200 g^{-1} on material prior to harvest to 3.6 million g^{-1} after fermentation and APCs increased from 3×10^4 g^{-1} to 4×10^8 g^{-1}.[25] After fermentation, the heaps are turned over and the rooibos tea is dried for 1 to 2 days in the sun, sorted and graded and finally pasteurized with steam, followed by hot air drying (Section 36.3.5).

36.3.4 Spoilage Associations and Pathogen Hazards

Spoilage

Although many herbal infusions have high microbial counts, spoilage is rare as they typically have a low moisture content of 7% to 12% corresponding to a water activity of 0.4 to 0.6.

There are many reports on the microbial load on herbal infusions used for medicinal use, with the general and not unexpected conclusion that the load is high and variable, but there are few comparable data for herbal teas consumed as a beverage.[65] The European Herbal Infusions Association (EHIA) therefore collected microbiological data of *ca.* 1,000 samples of herbal teas from all parts of the world. The teas examined had not been fumigated. The data obtained for APC are shown in Figure 36-1 and represent the main varieties (chamomile, linden, mint, orange leaves, and verbena) and also minor varieties of teas; data for molds are also presented in Figure 36-1. For yeasts, numbers ranged from 10^2 to 10^7 g^{-1}, with counts on mint in excess of one million g^{-1} (data not shown).

Pathogen Hazards

Salmonellas are generally not found in herbal drugs or teas.[3,44,46,47,65,75,95] However, Frank[30] refers to a survey of 374 samples of herbal tea in which 1.3% were contaminated with salmonellas. Bockemühl[12] reported finding *S. schwarzengrund* in a sample of peppermint, and Eckner et al.[26] reported salmonella in 4 out of 10 samples of lemon verbena (MPN 0.004 g^{-1}). The general low incidence of salmonellas in herbal tea is in line with the findings of Unilever Research.[57] Some strains isolated were *Salmonella montevideo* and *S. london* from linden tea, *S. weston* from verbena, *S. typhimurium* from mint, and *Salmonella* (not typed) from rooibos tea.

The incidence of salmonella in rooibos tea, however, has been reported to be high with 20% to 100% of South African rooibos samples contaminated, some with multiple serovars.[66] The exact source of the contamination recorded in this study was not identified. However, contaminated dust, human handlers, contaminated water used in the fermentation stage, and excreta from insects, birds, or animals are all possible sources. In one particular study, more than 150 salmonellas (49 serovars) were isolated from rooibos over a period of 1 year. The predominant serovars were subspecies of *S. choleraesuis (S. choleraesuis salanae and S. choleraesuis arizonae)*, and it is suggested that lizards were the main source of contamination.[80] However, other serotypes isolated from rooibos tea suggest other sources of contamination including water and other animals.[66] The high prevalence of salmonella on rooibos tea led to the introduction of a steam decontamination process (Section 36.3.5).

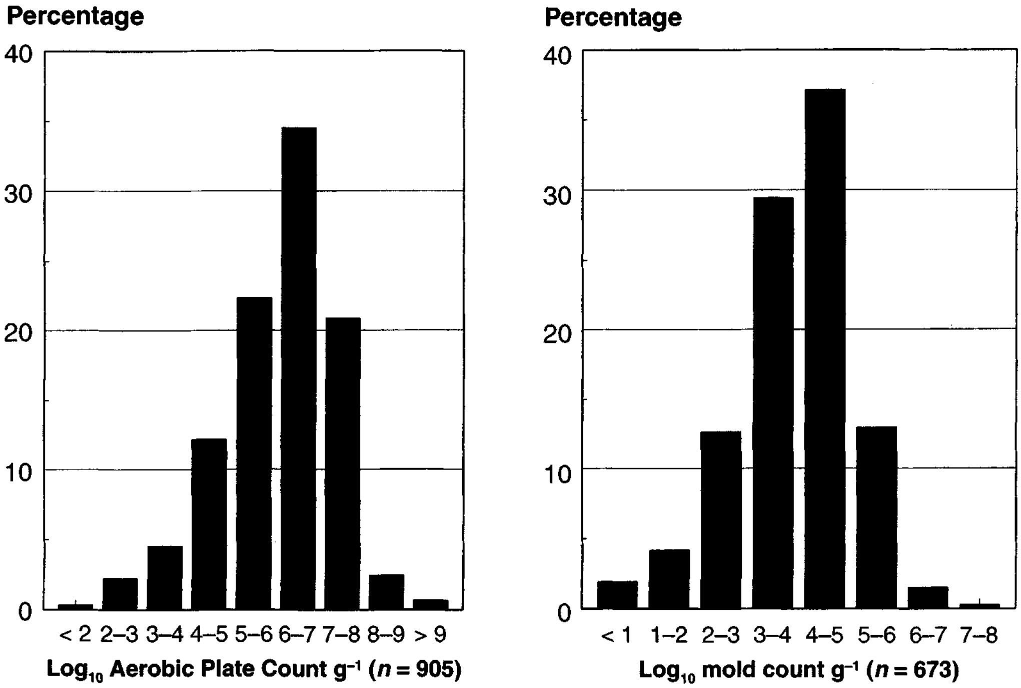

Figure 36-1 Aerobic Plate Count and Mold Counts of Nonfumigated Herbal Teas.

Other pathogens found contaminating herbal teas include *Bacillus cereus* (most teas have only a low load but chamomile often has a high load, typically 10^4–10^5 g^{-1}) and *C. perfringens*, which is present at low levels (10–1000 g^{-1}) in about 50% of teas, and occasionally at higher levels; bacterial spore-formers comprise 10% to 90% of the microbial flora of herbal teas. *Escherichia coli* may also be found and in the earlier mentioned EHIA survey most levels were low (73% below 100 g^{-1}) but 25% of samples had counts of 10^2 to 10^4 g^{-1} and a few above 10^4 g^{-1}. A low prevalence of *Staphylococcus aureus* was also reported.[30]

Herbal drugs and teas have been extensively examined for the presence of mycotoxins and, in particular, aflatoxins. Lutomski and Kędzia[50] examined 246 samples of 95 herbal drugs for aflatoxin B_1, ochratoxin A, and sterigmatocistin and failed to find these mycotoxins. These mycotoxins were not found in a Japanese study of 49 herbal drugs.[40] Aflatoxins were not found in other studies of herbal teas.[39,46]

36.3.5 Preservation

Because of their low moisture content, herbal teas are well preserved. However, in view of their often high microbial load, and the possible presence of pathogenic microorganisms, the effect of procedures used to prepare these teas for consumption has been studied extensively.[10,23,33,38,46,65,85,89,95] Boiling water was used in most of these investigations but water at 80°C was included in studies at Unilever Research. Filter bags of chamomile and mint with a natural contamination of 1 million Enterobacteriaceae g^{-1} were infused for 5 minutes and the resultant drink (and also the filter bag) analyzed for Enterobacteriaceae; no survival was observed.[57]

The conclusion from these studies is that herbal infusions when properly prepared, ie, by using boiling water, are microbiologically safe. Attention must therefore be given to providing clear instructions on packs like "Prepare with boiling water"; or a set of pictograms giving the same message. Instructions on some medicinal teas, which refer to the use of "hot water," will not ensure safety and should not be used.

Once prepared, infusions should be consumed shortly thereafter because surviving spore-forming bacteria may grow in the prepared drink when stored for over 24 hours at ambient or higher temperatures.[23,46,95] *Bacillus cereus* multiplied from 66 cells ml^{-1} to 2.5×10^5 ml^{-1} in a properly prepared chamomile tea stored for 24 hours at 30°C; no growth was observed in infusions of mint and linden prepared and stored under the same conditions.[57]

To illustrate the need for proper and suitable instructions for preparing herbal teas, an instruction for a medicinal drug (*Harpagophytum procumbens* DC 1) is presented below to illustrate an instruction that is **not suitable** for herbal teas:

> "Devils Claw tea should be prepared in the evening and allowed to stand overnight so that it may brew and develop its full effects. Place the filter bag in a glass or porcelain pot and add ¾ pint of boiling water. Remove the filter bag next morning. Drink the tea, thus obtained, either cold or lukewarm in three equal portions, 10 minutes before morning, noon, and evening meals. Do not boil the tea."

Decontamination of Herbal Infusions. Ethylene oxide (EO) has been widely used to decontaminate the materials used in herbal teas. However, its use was banned in the European Union (EU) in 1990 because of concerns over the occupational safety hazards associated with its use. There were also some concerns over the presence of EO residues and the concomitant production of the mutagen ethylene chlorohydrin (ECH) in the fumigated material.[33,75] EO is still allowed to be used in some countries. For example, it is permitted in North America with the consumer hazards controlled by setting limits for residual levels of EO (50 mg kg^{-1}, US) or ECH (1,500 mg kg^{-1}, Canada).

An effective alternative to EO decontamination is irradiation.[21] Irradiation with ^{60}Co gamma rays at level of 5 to 10 kGy commercially sterilized chamomile flowers without loss of quality or chemical changes.[44,45] In South Africa, irradiation of rooibos tea is officially permitted and was used to decontaminate rooibos in the 1980s.[66] Irradiation studies of six varieties of herbal teas by the EHIA showed that a dose of 10–15 kGy was required to eliminate Enterobacteriaceae and that there was no effect of this treatment on the acceptability of the infusions.[32] Chile is another country where irradiation of herbal teas currently is permitted and used. Extrusion decontamination is also potentially applicable to herbal teas. Although the process is effective in killing microbial contaminants, the appearance of the infusions is affected.[67]

Steam treatment is the method of choice for decontaminating rooibos tea. In initial experiments to establish a suitable process, rooibos with a moisture content of 10%, 15%, and 20% was heated as a 5 mm layer in a steam cabinet at 99.5°C for 2 to 5 minutes. This reduced the level of coliforms from over 10^5 g^{-1} to <10 g^{-1}. The organoleptic quality was acceptable to the Rooibos Tea Board only for rooibos treated for 2 minutes at 10% moisture.[25] In a slightly different treatment (2 minutes at 92°–95°C, followed by drying at 36°–38°C) salmonella were not detected immediately after the heat treatment but were recovered from 60% of treated samples stored at 4°C for 33 weeks; salmonella were not detected in treated samples stored at ambient temperature or at 37°C.[70] Currently, all rooibos is pasteurized for 2 minutes at 90°C and meets a specification of salmonella absent in 25 g, *E. coli* maximum 20 g^{-1}, aerobic plate count maximum 50,000 g^{-1}, yeasts and molds maximum 5,000 g^{-1}.[9]

Microbiological Limits. A number of microbiological limits have been proposed and applied to medicinal and herbal teas (Table 36-2). Those of the EHIA[27] are based on a large database and used in Europe for the trade in herbal infusions.

36.4 COFFEE

36.4.1 Composition

Coffee is cultivated from a few varieties of the genus *Coffea* in tropical and subtropical areas of mainly Latin America, Africa, and India. The main varieties grown are *Coffea arabica* (*ca.* 75% of the world production) and *Coffea robusta,* a form of *Coffea canephora* (25% of world production).[43]

The coffee cherry or berry consists of an outer layer of pulp and an inner layer of mucilage in which two seeds (beans) are present. The mucilaginous layer is removed from the beans by natural drying to give "natural" coffee or by a wet fermentation process to give "washed" coffee. The purpose of fermentation is to remove the mucilage pulp around the beans and not the development of coffee flavor. "Washed" coffee is of superior quality to "natural" coffee.

36.4.2 Effect of Processing

For "natural" coffee production, the berries are ripened on the tree, harvested, slowly dried to 13% moisture or less, and the pulp layer and skin removed by hulling.[17] The "washed" coffee process consists of a number of steps: (1) classification (cleaning), by flotation of the berries; (2) pulping, to remove the skin and the pulpy layers around the beans; (3) fermentation, in large tanks; (4) drying; (5) hulling; and (6) grading/sorting.[17]

During fermentation, the pectin and pectic acid from the mucilage are broken down by a variety of

pectinases produced by molds, yeasts, and bacteria. Jones and Jones[43] give an extensive overview of the literature and refer to studies on Hawaiian coffee where Gram-negative bacteria such as *Klebsiella* species (formerly *Erwinia dissolvens*) were predominant; the same was true for African coffee berries. For Brazilian coffee berries, the main organisms were reported to be coliforms, resembling *Enterobacter* and *Escherichia.* Molds including *Penicillium, Fusarium, Cladosporium,* and *Aspergillus* were also found on Brazilian coffee berries. Pectinolytic yeasts (*Saccharomyces* and *Schizosaccharomyces)* formed the largest part of the microbial population on fermenting Indian robusta coffee.

Fermentation is carried out in large, deep tanks. The upper part provides aerobic conditions and the lower, anaerobic conditions, which are best for coffee quality.[43] The fermentation is rapid and the mucilage is degraded in 7 to 8 hours at ambient temperature, with fermentation typically complete in 24 hours. During fermentation, ethanol and acetic, lactic, propionic, and butyric acids are formed, and the pH is reduced from an initial pH of *ca.* 6.0 to 3.7. Prolonged fermentation of Colombian coffee cherries resulted in an increase in acetic acid (and later also formic acid), and in a vinegar-like taste after 68 to 110 hours and a "stinker" defect after 140 hours. Predominant organisms during overfermentation were lactic acid bacteria and anaerobic bacteria.[49]

After completion of fermentation, the residual mucilage is removed, fermentation is stopped by washing, and the coffee beans are dried. Drying to 10% to 11% moisture is achieved by sun drying (about 8 to 10 days) or by hot-air drying in a mechanical dryer or a combination of the two.[16] The dried beans are thereafter hulled to remove the parchment surrounding the green coffee beans. The graded and sorted beans are sold in sacks, bags, or containers. They are blended, roasted, and sold as roasted coffee, or ground and extracted to give instant coffee or instant decaffeinated coffee. They may also be sold as sterilized liquid coffee in cans. For instant coffee, the roasted and ground coffee is extracted with hot water in a series of percolation batteries and the concentrated extract spray or freeze dried. Details of these processes are described by Clarke and Macrae.[17]

36.4.3 Spoilage Associations and Pathogen Hazards

Spoilage

During extended fermentation, microbial degradation of the coffee beans may occur resulting in poor quality coffee with onion-like flavor or even "stinker" beans.[49] Microscopic observations of defective beans revealed bacteria (*Bacillus brevi*) in stinker beans, yeasts and molds (*Eurotium*) on beans with an earthy flavor, and molds (*Aspergillus*) and bacteria on beans with a moldy flavor.[22] The dried coffee beans are hygroscopic and mold growth with the formation of off-flavors may occur when the drying of "natural" coffee is not well controlled.[84]

"Washed" coffee is also sensitive to moisture and moisture levels over 12% to 13% during storage and distribution may lead to moldy beans.

The microbial load on raw and roasted coffee was analyzed by Mohr.[59] Raw coffee beans had microbial counts of 5–8 × 10^4 g^{-1}. Freshly roasted coffee was nearly sterile, whereas retail roasted coffee had counts up to 4–7 × 10^3 g^{-1} indicating recontamination after roasting. Coliforms, yeasts, and molds were not observed. The microflora of instant coffee consisted of over 90% of lactobacilli with *L. plantarum* and *L. brevis* as the predominant organisms.[90] The lactobacilli apparently develop in the wet concentrate before it is dried. *Lactobacillus plantarum* was able to grow in the presence of 50% total coffee solids but was inhibited by adding 15 mg pure caffeine ml^{-1} to the concentrate. Growth of *L. plantarum* in reconstituted coffee gave off-flavors and a reduction in pH from 5.2 to 4.4. *Escherichia coli, Salmonella* spp., *S. aureus,* and *B. cereus* were unable to grow in 2% solutions of decaffeinated and nondecaffeinated coffee and died within 24 hours.[90]

Pathogens

The presence of food poisoning bacteria has not been reported for coffee beans. Toxigenic molds such as *Aspergillus ochraceus, A. flavus,* and *A. versicolor* and *Penicillium cyclopium, P. citrinum,* and *P. expansum* are common on green coffee beans.[58] Mycotoxin formation in coffee beans has been studied extensively. Aflatoxin has not been found in the past[31] due to the presence of caffeine, which inhibits growth of *Aspergillus parasiticus* and the formation of aflatoxin.[13] The same is true for sterigmatocystin.[11] Nevertheless, trace amounts (ng kg^{-1} and not μg kg^{-1}) of aflatoxin B1 were recently found in Arabica coffee from Yemen (2.4 to 20.2 ng kg^{-1}) and robusta coffee from Indonesia (2.9 to 32.9 ng kg^{-1}).[61] Trace amounts of ochratoxin A (OA) are often detected. Studies on the fate of OA during roasting are inconclusive. An early US study concluded that the incidence of contamination of the green beans is low, that 70% to 80% of the toxin is destroyed during roasting, and therefore the probability of finding OA in a coffee drink is very low.[48] In an Italian study, 58% of green coffee samples were contaminated with OA at 0.2 to 15 μg kg^{-1} but roasting gave significant destruction (from 48% to 100%) and brewed coffee contained no residual toxin.[55] However, recent studies[79] on the effect of roasting on the destruction of OA (initial levels 1.2 to 56 μg kg^{-1}) gave reductions of only 30%, and OA was found in 16 out 40 samples of brewed Swiss coffee; amounts were low and only 4 samples had values over 2 μg kg^{-1} (maximum 7.8 μg kg^{-1}). A survey of 291 samples of green (unroasted) coffee imported into the United Kingdom (UK) showed that about 200 were not contaminated with OA and only low levels were detected in the rest. Only three samples had more than 10 μg kg^{-1} and levels were not considered to be of concern.[51] A proposed EU limit of 4 μg kg^{-1} is under discussion.

36.4.4 Preservation

Properly processed beans with a moisture content of 12% are microbiologically stable. However, a value of 12% moisture is close to the limit of acceptability, because depending on the coffee variety and temperature, the water activity is 0.60 to 0.77. At such relatively high water activities, small temperature changes during transportation may result in local condensation and mold growth.[17]

Studies with wet-processed Arabica coffee stored at 20°, 25°, 30°, and 35°C at 60%, 75%, 85%, 90%, and 95% relative humidity (RH) gave rapid mold growth at 85% RH and above and slow growth at 75% RH especially at higher temperatures.[60] This and other studies indicate that storage of green beans at 75% RH results in coffee with acceptable organoleptic quality even when there is some development of molds, because the latter are inactivated during roasting. A moisture content of 15% for green beans is considered a practical upper value above which quality problems may occur.

Coffee has antibacterial activity against a range of pathogens including *S. aureus, V. parahaemolyticus, V. cholerae,* and *Salmonella*.[52,78,87] The antibacterial effects have been attributed to tannins and caffeine but the main effects are due to the degree of roasting of the coffee beans and the chemical compounds resulting from the Maillard reaction, caramelization, and thermal decomposition. The inhibitory activity could be demonstrated in regularly prepared coffee extract.[19,20]

The antimicrobial activity of coffee does not prevent the flat-sour spoilage of sterilized canned liquid coffee by thermophilic anaerobes.[62,63] The organisms were identified as *Desulfotomaculum nigrificans* and *Clostridium thermoaceticum*. Closer identification suggests that the reported *D. nigrificans* isolates also were strains of *C. thermoaceticum*.[64] Spores of *C. thermoaceticum* were extremely heat-resistant with $D_{120°C}$ of 6 to 25 minutes and $D_{121°C}$ of 44 minutes.[54,63] Sugar has been identified as a source of these spores.[82] For canned liquid coffee, which is sold hot from vending machines, suitable raw materials and a sterilization process of F_0 15 to 20 are recommended.

36.5 CONCLUDING REMARKS

Tea and coffee have in common an excellent public health status because of the absence of microbiological hazards in the materials and the use of boiling water in their preparation. Herbal teas have the same good reputation, however, they typically have a high microbiological load, which may include organisms of public health significance. Preparation with boiling water is thus recommended to ensure the safety of the prepared drink. Longer term, the microbial contamination of herbal tea raw materials should be reduced by the application of good agricultural practice (GAP) in growing and harvesting of the raw materials. The European Herbal Infusions Association is implementing GAP through a Code, which is available in various languages, to support hygienic practices in the countries of origin of herbal teas.[28]

For tea there is growing evidence that it is not only a safe and refreshing drink but tea may also have beneficial health effects. For example black and green tea contain substances that have *in vitro* very strong antioxidant activity, and these flavonoids are expected to have anticarcinogenic properties and to reduce coronary heart disease. This is a topic that will be actively researched in the near future, in particular for green tea, which has the higher level of antioxidants.[83,86] A recent CRC special issue: *Tea and Health* provides an overview of the scientific information to date.[18]

37.1 INTRODUCTION

Surveillance has been defined "as the continuous, systematic collection, collation and analysis of data and the prompt dissemination of the resulting information to those who are empowered to take appropriate action,"[3] and is an essential element of any food safety program, providing data on the prevalence of foodborne infection in man, in food-producing animals, and throughout the food chain.

Foodborne infections have been a major cause of human disease for centuries, yet they remain greatly under-reported and their true incidence unknown. Various studies have indicated that foodborne diseases may be approximately 300–350 times more common than reported cases indicate. It is only within the past 20 to 25 years or so that there has been a renewed awareness of their public health importance and the need to develop surveillance programs. Some impetus was given during the 1980s for improved surveillance following major outbreaks of listeriosis in Switzerland,[15] the United States (US),[53,87] and Canada.[146] Surveillance of foodborne disease since has been increasingly developed in many countries worldwide with varying national resources determining the extent and sophistication of programs undertaken. The World Health Organization (WHO) has drawn attention to foodborne disease as a worldwide problem and the role of surveillance as an essential step toward the introduction of control measures.[188]

Foodborne disease also has acquired a further international dimension with outbreaks affecting tourists from northern hemisphere countries holidaying in the Caribbean, the Mediterranean littoral, Southeast Asia, and elsewhere. In Scandinavia, for example, routine surveillance has indicated that between 78% to 86% of salmonella cases and 60 to 70% of campylobacter cases reported annually involve tourists returning from such areas.[121] In addition to outbreaks affecting tourist groups, other outbreaks have been reported from northern Europe and North America associated with imported foods such as chocolate, bean sprouts, salami sticks, savory snacks, eggs, pasta, and cheese.

While recent decades have seen many advances in food technology and food hygiene standards and the introduction of numerous legislative control measures, the incidence of reported foodborne disease has increased significantly in most countries, particularly since the early 1980s. Statutory notifications of food poisoning in the United Kingdom (UK), for example, increased four-fold between 1982 and 1994, with the number of laboratory reports of salmonellosis, campylobacter enteritis, verotoxin-producing *Escherichia coli* (VTEC), and other foodborne infections increasing in parallel.[122] A 1989 review in North America drew attention to the increase in reported infection due to *Salmonella enteritidis*, *Campylobacter*, and VTEC, and to the increasing health care and litigation costs of foodborne disease.[169]

Greater awareness among primary care physicians, the availability of new laboratory technologies, improved reporting, and the development of national and international surveillance programs have undoubtedly contributed to these increases. Enhanced laboratory identification and isolation techniques have resulted in the reporting of "new" foodborne diseases such as campylobacter enteritis, viral gastrointestinal infections, and VTEC, while the increasing use of computerized databases has undoubtedly enhanced the comprehensiveness of surveillance programs. Other factors such as periodic media publicity in relation to salmonella and eggs, VTEC ("hamburger disease") and listeriosis, for example, may also have affected the number of samples submitted to laboratories by physicians, thus further influencing reported incidence rates. While much of this may be due to increased awareness, detection, and reporting, nevertheless a real increase in incidence, in particular of foodborne infections of animal origin (eg, salmonella, campylobacter, VTEC) would appear to have taken place in many countries.

Surveillance programs have identified problems associated with specific areas of food production (eg, dairy, shellfish, egg-laying) and catering (eg, airline, sandwich bars), and among specific population groups such as school and nursery children,[47] the elderly,[42] hospital patients,[26] farm workers,[54] and other consumers of raw milk.[150] Local surveillance in several urban areas in the UK in the early 1990s identified an epidemiological association during the early summer weeks between campylobacter illness and the consumption of milk from bottles delivered to doorsteps, the metallic caps of which had been attacked by wild birds, in particular jackdaws and magpies.[71]

The most important objectives in surveillance are:

1. the detection of increases in incidence or changes in the pattern of disease, thus enabling early investigation of outbreaks
2. the monitoring of trends to assess the need for intervention or to evaluate the effect of control measures.[57]

To measure the incidence, prevalence, and trends of any disease condition (acute or chronic, communicable or noncommunicable, foodborne or nonfoodborne), it is necessary to obtain and analyze relevant epidemiological data. The three basic steps in any surveillance program therefore consist of:

1. the regular reporting and collection of data
2. the collation and analysis of data
3. the dissemination of the information

The introduction of computerized databases and electronic communication systems in foodborne surveillance has greatly enhanced the collation, analysis, and distribution of epidemiological data, nationally and internationally.

37.2 REPORTING AND COLLECTION OF DATA

37.2.1 General Review

Surveillance may be undertaken at regional, national, or international level, with the collection of data obtained by passive (the most common) or active methods, depending on perceived importance and the degree of urgency in obtaining epidemiological information on specific disease problems. Considerable differences also may exist as to which foodborne infections (or disease syndromes) are regarded as of sufficient importance to be included in individual national reporting systems (Table 37–1).

While salmonellosis predominates as the most commonly identified infection in most countries, other foodborne diseases vary widely in their reported incidence. Outbreaks of food poisoning due to enterotoxin-producing *Staphylococcus aureus* and *Clostridium perfringens* continue to be reported commonly in most of continental Europe[121] (Table 37–2) and predominate in Latin American countries such as Cuba and Brazil.[172] Brucellosis is prevalent in most Mediterranean countries, while trichinellosis and botulism are public health problems in much of Eastern Europe. Campylobacteriosis, the most frequently reported cause of human gastroenteritis in the UK, the Netherlands, Canada, Australia, New Zealand, and in some regions of the US, remains uncommonly

reported elsewhere. Infection due to *Campylobacter* usually occurs as sporadic cases, and outbreaks are relatively infrequent. VTEC infection (mainly due to *E. coli* serogroup O157), first recognized in Canada in the late 1970s, until recent years was reported infrequently by countries outside North America and the UK.

Most data collection systems are based on the laboratory reporting of isolates of foodborne pathogens; the reporting by physicians of prescribed infections (eg, botulism, cholera, listeriosis, typhoid) or clinically based disease syndromes (eg, food poisoning, infectious enterocolitis, gastroenteritis, hemolytic uremic syndrome); and/or the epidemiological investigation of outbreaks. Other data sources increasingly being used include physician "sentinel" and community studies (sections 37.2.4 and 37.2.5). Surveillance of foodborne disease can further be complemented via microbiological data obtained from (1) routine or ad hoc monitoring of foods (milk, water) by local health authorities from within the food industry (poultry broiler, dairy farming) or from surveys of specific at-risk foods (cold meats, shellfish, soft cheeses, pâté, salads), (2) monitoring of abattoir effluents, and/or (3) veterinary reports of sick food animals.

As a consequence of increased international awareness of the health and economic effects of foodborne disease, in 1980 WHO implemented the multinational Surveillance Programme for the Control of Foodborne Infections and Intoxications in Europe, the aims of which are

- identification of the causes and epidemiology of foodborne diseases in the European region of WHO
- distribution of the information gathered and collated to those concerned
- cooperation with national authorities in their efforts to strengthen the prevention and control of foodborne diseases (Table 37–2).

Table 37–2 WHO Foodborne Disease Surveillance Programme in Europe—Top 10 Etiological Agents Reported in Outbreaks by Participating Countries, 1990–1992

	Number of Outbreaks	(%)
Salmonella spp.	9,882	(84.5)
Staphylococcus aureus	409	(3.5)
Clostridium perfringens	356	(3.0)
Trichinella	181	(1.5)

The WHO program has two component parts: annual reporting by participating countries and an adhoc early warning system relating to international foodborne disease emergencies, such as outbreaks associated with foods imported from one country to another. The Food and Agriculture Organization (FAO)/WHO Collaborating Centre of the Federal Institute of Health Protection of Consumers and Veterinary Medicine, Berlin, serves as the coordinating center, collating national and international data on foodborne disease. Despite the considerable political change in recent years in Eastern Europe, with disruption of national health systems, surveillance, and reporting of foodborne disease, by 1998, 38 countries were contributing to the program.

A similar international collaborative reporting system has been developed in Australasia, where the Communicable Disease Control Network of Australia and New Zealand, based on a semiformal agreement between the two countries, routinely exchanges epidemiological data.

Foodborne disease was defined for the purposes of the WHO program as "a disease of an infectious or toxic nature caused by, or thought to be caused by, the consumption of food or water" and an outbreak as "an incident in which two or more persons experience a similar illness after ingestion of the same food, or after ingestion of water from the same source, and where epidemiological evidence implicates the food or water as the source of the illness" (Exhibit 37–1).

Despite agreement in principle to accept these definitions, they are not always fully complied with by individual countries within Europe. In some countries, outbreak reporting is required only when three or more people have been affected. Further differences also exist. In some countries a disease is regarded as being foodborne only when the causative agent has been identified in both affected individuals *and* in the food consumed. Some countries accept epidemiological evidence, and others include all reported cases of acute diarrheal disease regardless of whether it is foodborne or not. Comprehensiveness

Exhibit 37–1 WHO Definitions of Foodborne Disease

Foodborne disease—a disease of an infectious or toxic nature caused by or thought to be caused by the consumption of food (or water).

Single (sporadic) case—one case, as far as can be ascertained, unrelated to other cases in respect of consumption of food (or water).

Household outbreak—an outbreak affecting two or more persons in the same private household, not apparently connected with any other case or outbreak.

General/community outbreak—an incident in which two or more persons experience a similar illness after ingestion of the same food (or after ingestion of water from the same source), and where epidemiological evidence implicates the food (or water) as the source of illness.

of investigation and reporting also varies considerably within and among different countries, largely due to differences in perceived priorities and commitment to surveillance. Comparability of collected data thus presents considerable problems.

It has been estimated that officially recorded data probably represent less than 10% (tip of the iceberg) of the real incidence of foodborne disease occurring in the community in countries with developed surveillance systems (Figure 37–1). Whereas the more clinically severe infections (eg, typhoid, listeriosis, botulism) usually require admission to hospital and thereby are more likely to be diagnosed, reported, and recorded, most others (eg, non-typhoid salmonella, campylobacter) may be self-limiting with a smaller proportion of cases seeking medical attention. In a study relating to problems affecting the diagnosis of foodborne disease in Wales, only 1 in 26 people suffering an acute episode of gastroenteritis consulted their family physician.[105] Furthermore, the physician may not arrange for a fecal specimen to be sent for laboratory examination or to notify the local health authority. Viral infections in particular are very much under-reported and the responsible etiological agent is even less likely to be identified. Not only is the illness usually of relatively short duration with the patient recovering within 24 to 48 hours, but even when a viral diagnosis is considered, it is essential that fecal specimens are sent to the laboratory within 24 to 48 hours of onset of symptoms. Viruses are cleared from the stool within 1 to 2 days and identification depends on the availability and utilization of electron microscopy or detection methods based on polymerase chain reaction (PCR) assays (see Chapter 52).

The disparity in the national salmonella isolation rates recorded in the UK (22 to 59 per 100,000 population) and in the US (13 to 22 per 100,000) between 1984 and 1995 appears to be due to differences in the comprehensiveness of reporting by laboratories to the respective national databases through the Public Health Laboratory Service (PHLS) Communicable Disease Surveillance Centre (CDSC), London; the Scottish Centre for Infection and Environmental Health (SCIEH), Glasgow; and the US Centers for Disease Control and Prevention (CDC), Atlanta, rather than to any major differences in disease incidence. An even greater disparity is seen for campylobacter infection with reported UK national isolation rates of 40 to 84 per 100,000[122] compared with reported US national rates of 5 to 6 per 100,000.[124,163] However, in the US, where laboratories in some areas of the country were routinely screening diarrheal feces for *Campylobacter*, isolation rates up to 71 per 100,000 were recorded.[16,124,149]

Within the UK during the 1970s and early 1980s, higher salmonella rates were observed in Scotland (33 to 51 per 100,000) than in England and Wales (21 to 31 per 100,000) and Northern Ireland (NI) (4 to 6 per 100,000). In Scotland, integrated interdisciplinary salmonella surveillance with isolates of all *Salmonella* species from medical, veterinary, and commercial (eg, poultry broiler industry) sources processed by one reference laboratory (the Scottish Salmonella Reference Laboratory, Glasgow) has been a feature since the early 1970s (Figure 37–2). Concurrently with the increasing awareness of the emergence of infection by *S. enteritidis* phage type 4 throughout the UK, the number of reports of enteropathogens received by CDSC from hospital laboratories (ie, outside the PHLS) in England and Wales doubled between 1985 and 1995. During this time, the different sources of information on human salmonellosis in England and Wales were amalgamated into a single data set.[55] Salmonella isolation rates comparable with those recorded in Scotland were reported thereafter.[122]

Surveillance programs for infection due to *E. coli* O157 have been increasingly developed in recent years in many countries, in some of which (eg, Australia, Canada, New Zealand, Sweden, US) the disease has been made notifiable. Surveillance of the hemolytic uremic syndrome (HUS) and non-O157

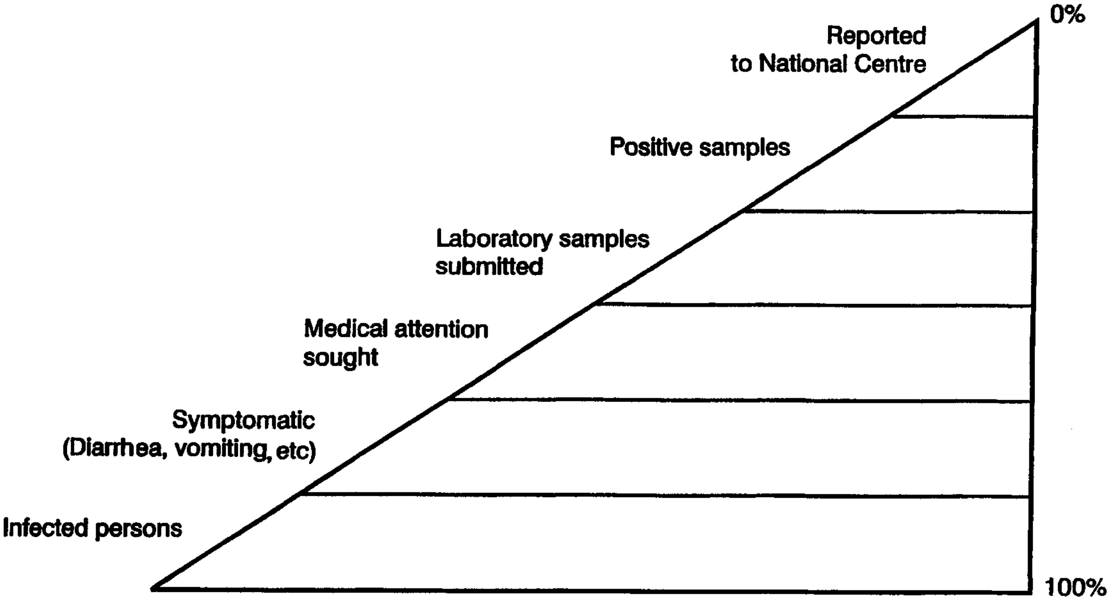

Figure 37–1 Foodborne Disease "Iceberg"—Estimated Prevalence in the Community

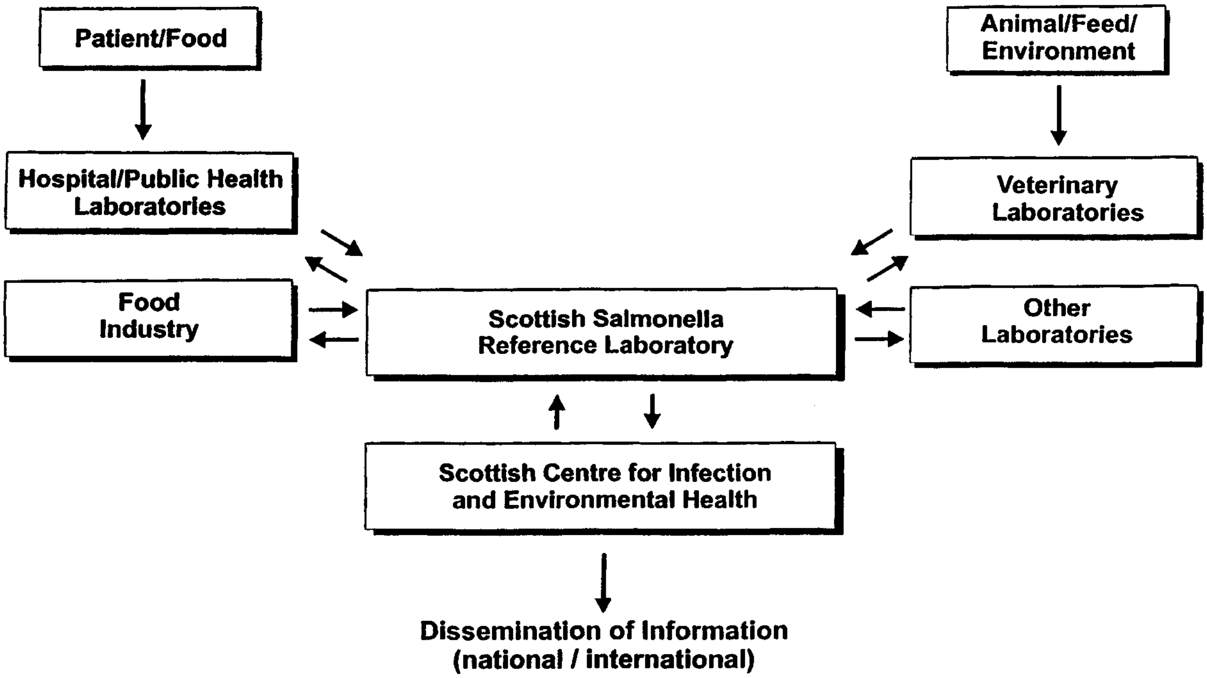

Figure 37–2 Salmonella Surveillance in Scotland—A Schematic Representation

VTEC infections due to serogroups that ferment sorbitol (and therefore are unlikely to be detected by the routine use of sorbitol-MacConkey [SMAC] medium), however, have been less well developed to date.

Epidemiological data sources used in surveillance can differ considerably from country to country. In the UK, the three main sources for reports of foodborne disease are: (1) notifications of food poisoning, (2) the reporting of laboratory-confirmed infections, and (3) the reporting of general outbreaks of infectious intestinal disease. In England and Wales, the data from all three sources are coordinated by CDSC[181] and in Scotland by SCIEH. Within Wales, a three-tier arrangement (local, regional, and national) for communicable disease surveillance, CoSurv, based on laboratory-confirmed infections, has been developed that links laboratories, public health, and environmental health departments with each other and with the regional and national surveillance centers based in Cardiff and London. CoSurv, has now been installed in all PHLS laboratories and regional surveillance centres throughout England and Wales.[66] In 1997 a collaborative project was initiated involving CDSC and SCIEH toward the development of an enhanced standard surveillance system for the investigation and reporting of cases of food poisoning throughout the UK.

In the US, the collection of surveillance data has been based primarily on state and federal legislative requirements to report prescribed foodborne diseases, in parallel with voluntary reporting to CDC of outbreaks as well as specific infections (eg, listeriosis, campylobacteriosis). Similar legislative reporting arrangements also are featured in Australia, Canada, and New Zealand. In January 1996, as part of a wider strategy in the US (Emerging Infections Program), a foodborne diseases active surveillance network (Food Net) was implemented by CDC in several states (Minnesota, Oregon, California, Connecticut, Georgia), the objectives of which are to: (1) determine more precisely the burden of foodborne diseases in the US, (2) determine the proportion of specific foodborne diseases associated with certain foodstuffs or with other exposures, and (3) provide the framework to respond rapidly and collaboratively to emerging foodborne diseases.[149] Surveillance was extended in January 1997 when laboratories in several counties in Connecticut and Georgia joined Food Net.

In the Netherlands, two official notification systems exist:

1. the mandatory reporting of notifiable diseases and outbreaks involving two or more people to the chief medical inspectorate
2. the reporting of complaints by individual members of the public, concerning suspected food contamination, to regional food inspection services.

In recent years, however, increasing reliance has been placed on physician sentinel reporting (Section 37.2.4). In France, surveillance is based on data obtained through the French Communicable Diseases Computer Network (Le réseau national téléinformatique de surveillance et d'information sur les maladies transmissables) initiated in 1984, involving approximately 50 sentinel laboratories and 500 primary care practices across the country.[25,177] Collaborating physicians, laboratories, and local and national health departments connected to the network each have their own computer terminals (provided free of charge to participating physicians) with the potential of exchanging information on a 24-hour basis. Electronic bulletins summarizing surveillance data and regional statistics are produced weekly.

Surveillance systems differ in their strengths and weaknesses (Table 37–3) and need to be complemented by other reporting mechanisms to obtain the most meaningful epidemiological data. Notification of foodborne disease, despite specific legislative requirements, is not always complied with. In westernized countries, most cases of typhoid or shigellosis are spread by person-to-person rather than by food- or waterborne transmission, while in some instances campylobacteriosis, VTEC, and salmonellosis are due to zoonotic contact with infected animals or with a contaminated environment. Syndrome reporting (food poisoning, gastroenteritis) usually is based on a clinical opinion of the likely nature of the illness, which in fact may sometimes not be of microbiological origin or due to foodborne spread. Laboratory-based systems have a greater cost implication and are subject to selection bias being dependent on appropriate clinical specimens (feces, blood) being submitted by physicians and others, being successfully processed and the results reported to relevant regional or national surveillance centers. Outbreak investigation data vary widely in the comprehensiveness and quality of the investigation undertaken and the information provided, much of which is dependent on the interest and enthusiasm of individual investigators. Hospital admission data relate only to more seriously ill cases requiring hospital treatment. Physician sentinel and community

Table 37–3 Foodborne Disease Surveillance Reporting Systems: Basic Strengths and Weaknesses

System	*Strengths*	*Weaknesses*
Statutory notification	Legislative requirement. Clinical/laboratory evidence. Opportunity of early alerting by telephone, e-mail. May include confirmatory laboratory evidence (see also below).	Variations in comprehensiveness of physician diagnostic accuracy, regularity, and timeliness of notifying. Often unsupported by confirmatory laboratory evidence.
Reporting by hospital, public health (or other) laboratories	Confirmation of infectious or toxic agent. Further identification of etiological agent (serotyping, toxin-testing). High reporting level where good local/national collaboration. Detection of outbreaks. Monitoring trends.	Dependent on appropriate clinical material being submitted by physicians, etc. Policy and cost limitations in the range of culture methods. Specificity of diagnostic test(s). Time lag (7 days +) between onset of illness and report.
Physician sentinel studies	Front-line picture of clinical events. Comprehensive of those people seeking medical attention within participating practices.	Dependent on affected person seeking medical attention. Selected practices only. May or may not have confirmatory laboratory evidence.
Community studies	Truer estimate than sentinel studies of real extent of disease incidence in the community. Complemented by laboratory testing for possible etiological agent.	Dependent on collaboration of those persons participating. Undertaken over a limited time. Selected communities, expensive and time consuming.
Hospital admissions	Clinical evidence. Can provide early warning of an acute foodborne disease incident.	More seriously ill cases only likely to be admitted to hospital. Dependent on epidemiological awareness by hospital medical staff and good professional relationships with public health colleagues.
Outbreak reporting	Identifies occurrence of circumscribed outbreaks and enumerates numbers affected. Provides information on suspected (or confirmed) food vehicle(s), etiological agents, and reasons for outbreak.	Comprehensiveness of investigation and quality of data obtained dependent on the interest and enthusiasm of the investigator.

studies are expensive and time-consuming to organize and administer and most usually are undertaken over a limited time period. Passive surveillance is less costly than active surveillance, but is also less complete.

37.2.2 Statutory Reporting (Notification)

Statutory reporting (notification) of foodborne disease(s) by microbiologists or physicians is a legislative requirement in most countries, the primary purpose of which is to alert the public health authorities (preferably by telephone or by electronic means) so that the investigation of outbreaks and other incidents and appropriate preventive action can be undertaken as soon as possible. Data obtained also are used for longer term surveillance purposes at regional, national, or international levels (Figure 37–3). The collected data may take the form of reports of isolates of specific foodborne pathogens (*Salmonella* species, *Campylobacter* species) by laboratories or as syndrome reporting (food poisoning, gastroenteritis, infectious enterocolitis, HUS) by physicians, but the situation can vary from country to country. Within the US, Canada, and Australia, for example, legislative requirements can differ also from state to state or province to province compared with those required under national legislation. The comprehensiveness of reporting also can differ widely within individual countries from region to region, from

laboratory to laboratory, and from physician to physician. In some countries, for example, Cuba, the reporting of foodborne diseases is mandatory at all levels of the health system.[172]

In the UK, physicians have a statutory duty to notify the local health authority of cases (or suspected cases) of food poisoning, for which a fee (£2.30/$3.86 in 1998) is payable. Cholera, typhoid, paratyphoid, and viral hepatitis are also similarly notifiable, whether or not thought to be foodborne. Laboratory confirmation of an etiological agent is not necessarily required, although it may be available in many instances. In the absence of formal notification by a physician, food poisoning data can also include cases ascertained by other means such as in the course of an outbreak investigation or as a result of complaints by members of the public.

In North America, notification of specific foodborne diseases is mandatory within individual states and provinces. In the US, onward reporting of notifiable diseases by state health departments to the CDC is undertaken on a voluntary basis through the computer-based National Electronic Telecommunications System for Surveillance (NETSS). In Canada, there are similar legislative requirements for the notification of foodborne diseases, initially to the provincial health department and thereafter to the Laboratory Centre for Disease Control (LCDC) in Ottawa. Although *E. coli* O157 infection and HUS have been notifiable in some provinces (eg, Alberta, British Columbia) since the early 1980s, it was not until 1989 that VTEC infection (hemorrhagic colitis) was added to the list of diseases under national surveillance. In the US, *E. coli* O157 came under formal surveillance nationally in 1993, in addition to which an increasing number of states (eg, New Mexico, New York, Ohio, Texas) have also included HUS as a notifiable disease.

In Australia, most states generally have consistent legislation relating to which foodborne diseases require notification. Only New South Wales does not require the reporting of campylobacteriosis, shigellosis, or yersiniosis. HUS in children under 16 years is reportable by microbiologists and nephrologists to the Australian Paediatric Surveillance Unit, as well as to state health departments in the Northern Territory, Tasmania, and Western Australia. Syndrome reporting such as food poisoning, gastroenteritis in an institution, or in a foodhandler, is also required in some states.

In New Zealand since July 1996, salmonellosis, campylobacteriosis, listeriosis, viral hepatitis A, and outbreaks of food poisoning are reported by physicians to local environmental health departments, although in many instances in urban areas, epidemiological investigations are still undertaken by public health board staff. Onward reporting of data is undertaken via a computerized network to the Institute of Environmental Science and Research Communicable Disease Centre at Porirua, and then by e-mail to Canberra, Australia, as part of the Communicable Disease Control Network of Australia and New Zealand. National guidelines on surveillance, reporting, and investigation of food- and waterborne diseases were produced by the New Zealand Ministry of Health in 1994, including specific guidelines for the surveillance of mollusk-associated (shellfish biotoxin) disease.

In the Netherlands, there are two categories of statutorily notifiable diseases: group A (typhoid fever), which is required to be reported on clinical suspicion and group B (botulism, cholera, bacillary dysentery, paratyphoid, and incidents of foodborne infection or intoxication), which require a confirmatory laboratory diagnosis. In addition, foodborne disease has to be reported if the diagnosis is suspected among food workers, among people professionally nursing or caring for other people, or if two or more persons have developed similar symptoms within 24 hours after consuming the same food (or drink). Information obtained from these official systems has, however, generally been of poor quality and usually only related to outbreaks; as a result, increasing reliance has been placed on physician sentinel reporting to provide more accurate data. Salmonellosis, a common cause of foodborne disease in the Netherlands, was removed from the list of statutorily notifiable diseases in 1985; since then data have been collated from laboratory, sentinel research, and community studies.

In most European countries other than France, surveillance is based primarily on statutory reporting, although the legislative requirements for individual diseases may differ considerably from country to country (Table 37–1).

37.2.3 Laboratory Reporting

Laboratory-based surveillance systems provide definitive data relating to the isolation of pathogens from the feces (or other clinical material) of affected humans, as well as from food animals, food, and the environment. Laboratory surveillance is particularly useful in detecting outbreaks and monitoring trends. The reporting of laboratory-confirmed foodborne infections, a legislative requirement in many countries, forms an integral part of most surveillance programs. The surveillance of specific infections (salmonellosis, listeriosis, VTEC, *C. perfringens*) is further complemented by, or in some countries fully based on, epidemiological data provided by specialist reference laboratories. Some laboratories, in particular commercially-based private laboratories, may vary considerably in the comprehensiveness of reporting to surveillance centres and/or in forwarding isolates to appropriate reference laboratories for further characterization.

In the UK, voluntary reporting by laboratories (national health service, university, and PHLS) has formed the basis of foodborne disease surveillance since World War II, in parallel with statutory reporting (notification) of food poisoning, typhoid, paratyphoid, and cholera. In the US, reporting requirements for laboratories differ by state. Reports of isolates of foodborne pathogens (*Salmonella* spp., *Shigella* spp., and *Campylobacter* spp.) are forwarded thereafter on a voluntary basis to CDC through a computer-based surveillance system via the Public Health Laboratory Information Service (PHLIS), independently of NETSS. Whereas NETSS records disease categories such as salmonellosis, the PHLIS system provides more specific data relating to serotype (*S. enteritidis, S. typhimurium*). In Canada, voluntary laboratory reporting of non-notifiable enteric pathogens (eg, enteropathogenic and enterotoxigenic *E. coli, Bacillus cereus, Yersinia, Aeromonas*) to LCDC also is done. In Australia, laboratory reports of individual enteropathogens (*Salmonella* spp. and others) are collected by the National Salmonella Surveillance Scheme in Melbourne, and those from virus laboratories are collected by the Commonwealth Department of Human Sciences and Health in Canberra.

On numerous occasions, laboratory-based surveillance has detected and led to the control of community outbreaks of foodborne disease. Among these were the *E. coli* O157 apple juice[6,14] outbreaks in western US and Canada; listeriosis in Switzerland,[15] France,[60] US,[53,87] Canada,[146] and the UK;[93] cholera in Maryland, United States;[165] paratyphoid fever in France;[40] Norwalk-agent gastroenteritis in Louisiana and other states (Maryland, North Carolina, Mississippi, Pennsylvania, Texas) in the US;[46,80] shigellosis in Scandinavia[77] and in the UK;[5] and national and international outbreaks of salmonellosis in North America[19,34,65,141] and the UK.[31,59,78,138]

Laboratory-based surveillance programs are dependent, however, on the appropriate pathological specimens being submitted for testing and being successfully processed in the laboratory, and the results forwarded to the surveillance center. A 1993 study in England showed that only 5.4% of adults who had experienced a recent episode of diarrhea reported that a fecal specimen had been requested for microbiological examination.[49] A disproportionate number of fecal (and other clinical) samples are submitted from young children compared with from older children and adults. Age-specific isolation rates therefore may readily become distorted unless computerized databases recording the number of specimens examined in relation to the frequency of isolates by patient age-group (denominator data) are used by laboratories.

37.2.4 Physician Sentinel Studies

Primary-care physician-based sentinel studies for gastrointestinal disease are relatively uncommon compared with those for respiratory infections, but are being developed increasingly for surveillance purposes in some countries, in particular in the Netherlands, France, Australia, and the UK.

In the Netherlands, the first sentinel study, involving 40 general practices, two regional public health services, and two regional laboratories, was undertaken in the late 1980s. All people with acute gastroenteritis seeking medical attention were asked to complete a short questionnaire and submit a fecal sample for laboratory screening for *Salmonella, Shigella,* and *Campylobacter.* An incidence rate of 15 episodes of acute gastroenteritis per 1,000 persons per year was recorded.[100]

In France, the Communicable Diseases Computer Network collects data on seven selected non-notifiable disease conditions from 500 primary care medical practices throughout the country. Acute diarrheal disease was added to the list in 1990. In 1992, the second full year of diarrheal disease surveillance, 103,800 cases were reported, equivalent to an annual estimated incidence of 5,500 cases of acute diarrheal disease per 100,000 of the French population.[25] Since 1995 the collected data have been available electronically on the worldwide network (Sentiweb).[17] Although not geared primarily to outbreak recognition, sentinel surveillance led to the detection of an extended outbreak of acute gastroenteritis across four regions of the country (Ile-de-France, Bretagne, Rhône-Alpes, Pays-de-Loire) over a 10-week period during 1994–1995.[52]

In England and Wales, the Royal College of General Practitioners (RCGP) developed a sentinel practice scheme during the 1980s involving 60 general medical practitioners (GPs) and about 425,000 patients, for a range of clinical conditions including infectious gastrointestinal disease. The practices report weekly to the RCGP, with the collated data returned weekly to participating practices. Since 1986 a network of volunteer general practices (GP Surveillance of Infection in Wales Scheme) has operated in Wales,[104] reporting weekly on nine clinically diagnosed infectious diseases, including acute infectious gastroenteritis since 1990 and diarrhea with frank blood since 1995.

Following UK government recommendations,[118] a more comprehensive, in-depth epidemiological study of Infectious Intestinal Diseases (IID) (irrespective of whether or not foodborne in origin) based on 70 general medical practices was undertaken in England between July 1993 and January 1996, involving the Medical Research Council Epidemiology and Medical Care Unit, the Epidemiology Unit at the London School of Hygiene and Tropical Medicine, and the PHLS. The objectives of the study were to:

- estimate the etiology and incidence of IID both in the population and presenting to GPs
- compare these numbers and etiologies with those recorded by the national surveillance system
- estimate the prevalence of asymptomatic infection with agents associated with IID
- document differences between cases of IID and similar but well people (controls)
- estimate the socioeconomic costs of IID.

Although the purpose of the study was to provide insights into the causes of IID, its design was not intended to monitor trends, but rather to provide a more accurate estimate of the relationship between the real incidence of IID and that detected by routine national surveillance.

In addition to the main study, there were four secondary studies to ascertain the number of IID cases presenting to hospital accident and emergency departments, the long-term medical sequelae of IID, the completeness of reporting of enteropathogens by laboratories in England to the national surveillance centre (CDSC), and the completeness of the ascertainment of IID by GPs. An interim report was published in 1996, followed by the final report in 1999.

A prevalence study in two urban general practices in Scotland indicated that 12% of people seeking medical attention had reported diarrheal symptoms involving some loss of time from school or work in the 3-month period prior to being interviewed.[157] A more recent study of acute gastrointestinal infection presenting to GPs across Scotland began in May

1996, embracing a population of about 150,000, with fecal samples examined for common enteropathogens by a single laboratory.

In Australia, the Australian Sentinel Practice Research Network, comprising 99 general practices throughout the country, reports weekly on 12 acute medical conditions including gastroenteritis. Although used in some Canadian provinces, sentinel physician reporting has not yet been developed to any extent in the US.[163]

37.2.5 Community Studies

Compared with physician sentinel studies, which are based on those people who seek medical assistance, more accurate assessments of the incidence of gastroenteritis can be provided by community studies, the first of which were undertaken in the US during the 1950s.

Community studies have been developed further in some European countries. A 1991 study in the Netherlands in four different geographic regions of the country involving a sample of about 1,500 persons randomly selected from each of the population registers of the four regions showed that of those who reported having experienced symptoms, only 20% had consulted a physician in person or by telephone.[69] A similarly structured community study was undertaken in England during 1993–1996 as part of the extensive IID epidemiological study.[173]

Although adding further to costs and administrative input, more definitive epidemiological data are obtained from studies supported by microbiological investigations.

37.2.6 Hospital Admission Records

Admission records of ill persons requiring treatment in hospitals, irrespective of whether or not a definitive clinical or microbiological diagnosis has yet been made, can provide useful early indication of the occurrence of acute gastrointestinal disease in the community. The first indication of an outbreak of foodborne disease[13,21–23,101,176] may be the admission to a hospital of groups of people presenting with similar clinical (diarrhea, vomiting, fever, HUS) or epidemiological histories (attended the same playgroup, members of the same social or ethnic group).

Hospital discharge records or death registration of individual patients also may provide useful, albeit limited, retrospective data of the more serious foodborne diseases (eg, botulism, VTEC).

37.2.7 Outbreak Reporting

Outbreak reporting is a fundamental feature of surveillance in most countries and in some (eg, the Netherlands, New Zealand, France, Spain) is a legislative requirement. Outbreak reporting data are, however, heavily dependent on the quality of the original investigations, the standardization of laboratory methods, and the consistency of reporting.

Although contributing within Europe since 1980, the surveillance of outbreaks in the UK has become standardized only since the early 1990s. In the US, CDC initiated national surveillance of foodborne disease outbreaks in 1966. Outbreaks most usually are reported to CDC by state and local health departments, although they may also be reported by federal agencies such as the US Food and Drug Administration (FDA), the US Department of Agriculture, and the US Armed Forces, or occasionally by private physicians; outbreaks occurring on cruise ships or associated with food eaten outside the US are not included. Summaries of reported outbreaks are published every 5 years.[12] The Canadian Foodborne Disease Reporting Centre of the Federal Health Protection Board, Ottawa, began collecting and publishing information on outbreaks in 1973.[171] These data are generally more complete than in the US because each of the 10 Canadian provinces and territories reports annually to Ottawa.

The WHO Surveillance Programme for Control of Foodborne Infections and Intoxications in Europe, primarily based on outbreak reporting, has provided useful epidemiological data since 1980[116,121] despite varying levels of input by participating countries, differing national data collection systems and definitions of outbreaks.

37.2.8 Other Sources of Information

Foreign Travel

Although the data usually are heavily biased toward those infections that are laboratory-confirmed, information from returning travelers has been used effectively for surveillance purposes. Additional information can be obtained also through questionnaires issued to travelers and collected in flight, at airports, or in the primary care setting. Such studies can include targeted groups, for example people who visit travel clinics for advice before travel, and can help monitor the effectiveness of the information given.

Gastroenteric infections, most of which are food- or waterborne in origin, constitute the bulk of disease reported. A survey in Scotland showed that *Salmonella* spp. are the most common enteropathogen isolated from returning tourists and other travelers from overseas; other infections reported included typhoid, paratyphoid, shigellosis, campylobacteriosis, giardiasis, entamoebiasis, and hepatitis A.[179]

Medical services specifically for overseas travelers are developing in an increasing number of countries. Many organizations audit their work and publish data that are coordinated by the International Society of Travel Medicine, whose journal also highlights specific food-related risks such as the consumption of unpasteurized goat's milk cheese.[67]

The Food Chain

Routine and ad hoc monitoring of the food chain from the farm to the consumer by environmental health, veterinary, and food protection authorities (Exhibit 37–2) provides important data relating to food contamination. Microbiological monitoring of foods is based on samples (eg, milk, water) submitted by environmental health officers (EHOs), veterinary, or other trained staff. The professional group responsible for sampling differs from country to country. In the UK, EHOs are mainly responsible; veterinarians are responsible in most of the rest of Europe.

In England and Wales, the PHLS Food Surveillance Group coordinates regular surveys carried out by its food chain (sentinel) laboratories of at-risk foods such as poultry meat, sausage meats, sliced meats, shellfish, prepacked sandwiches and salads, soft cheeses, airline meals, and cook-chill foods.[58,99,108,132] Inspections of retail chicken have demonstrated that salmonella contamination rates of frozen birds sampled decreased from 79% in 1979 to 41% in 1994 and of chilled birds from 54% in 1987 to 33% in 1994.[123,134] A study of frozen chicken carcasses in a hospital kitchen in Scotland identified salmonella contamination in 45% of birds and 100% of the weekly consignments examined.[114] Surveys in other countries have demonstrated similar contamination rates.[76]

More recently, laboratory food-chain surveys in England and Wales by the PHLS and the Ministry of Agriculture and Food have been commissioned to assess the extent of microbiological contamination (*Salmonella* spp., *Campylobacter* spp., *Listeria* spp.) within catering and retail premises, in particular studying food items such as (1) salads and hors d'oeuvres from self-serve salad bars, (2) UK-produced raw chicken, (3) cream cakes, (4) raw cow's milk and cheeses, (5) ready-to-eat meats and meat products, (6) warm water shrimp, and (7) cooked, dried, fermented, and mechanically recovered meats.

Exhibit 37–2 Some Environmental and Veterinary Food Surveillance Mechanisms

- Local health authority monitoring of foods (milk, water, etc.)
- Commercial monitoring of foods (poultry industry, dairy industry, etc.)
- Laboratory surveys of foods (cold meats, shellfish, etc.)
- Veterinary investigation of "ill" food animals
- Sewage (human)/abattoir (animal) effluent surveys

Campylobacter contamination rates of up to 100% of birds examined, particularly fresh birds, have been demonstrated in surveys of retail poultry carcasses in several countries including the Netherlands[178] and the UK.[68] In Australia, regulations were introduced in Victoria in 1990 requiring the notification of isolates of *C. jejuni*, *L. monocytogenes*, or *Salmonella* species from food for human consumption. In New Zealand, following the 1993 biotoxin outbreak, a national shellfish surveillance program, administered jointly by the Ministries of Health and Agriculture and the New Zealand shellfish industry, has been applied to both commercial and domestic gathering.

With the decrease of border inspections within the European Union (EU), food inspection authorities are confronted with a greater challenge in the prevention of multinational foodborne outbreaks. To help combat such dangers, the European Community Coordinated Food Control Programme has the responsibility of supervising microbiological (and chemical) sampling and analysis of food involving all 15 countries in the EU.[27] It is also required of member states that food control authorities responsible for sampling and analysis "shall have (or have access to) a sufficient number of suitably qualified and experienced staff, in particular in areas such as chemistry, food chemistry, veterinary medicine, medicine, food microbiology, food hygiene, food technology and law." Within individual countries, input to the program is coordinated by national food coordinating committees. Results are collected nationally, with the data being forwarded to Brussels for collation. At the time of writing, results from this program have not been published. Surveillance based primarily on locally perceived problems within individual member states is also carried out as required by the relevant environmental health, veterinary, or other food protection agencies. The European Commission coordinates a Rapid Exchange of Information for Foodstuffs (RAPEX), which ensures that where a food hazard (microbiological or chemical) goes beyond individual EU national borders, all other member states are alerted so that they may take any necessary action at a national level. All laboratories in the EU engaged in official food control work are required to be accredited for that purpose by November 1, 1998.

Veterinary Surveillance

Statutory surveillance of salmonellosis and brucellosis in food animals is required in the UK under the Zoonoses Orders of 1975 and 1989 and requires the reporting of any isolate of *Salmonella*[125] or *Brucella* in any "food animal or bird or animal surroundings or feedstuff."

The recent emergence of transmissible spongiform encephalopathies as potential foodborne zoonoses has led to the introduction of legislation that makes them reportable not only in the UK but also in the rest of the EU.[28] Surveillance of the major foodborne zoonoses in both animals and humans also takes place at the international level. In Europe the appropriate authorities (whether medical or veterinary) are required to make an annual submission to the European Commission on trends, sources, and control of zoonotic infections.[29]

Surveys have demonstrated fecal carriage of human enteropathogens such as *Salmonella* species and VTEC by domestic farm animals, particularly cattle. Abattoir surveys have shown correlations between asymptomatic bovine infection and fecal contamination of carcasses. Veterinary studies in the UK[159,160,174] and in Canada[115] have also demonstrated a direct link between cattle and human *E. coli* O157 infection. Surveys of abattoir and sewage effluents have also been used to monitor the prevalence of *Salmonella* in food animals, in local human populations, and in the environment, providing an insight into circulating serotypes and phage types.[75,86]

Other veterinary and commercial surveillance sources, not always accessible by the health authorities, can also provide useful epidemiological data. Monitoring of poultry flocks, processing plants, and products within the poultry industry, for example, can provide a timely insight into the organisms present within a major food product and to which the human population may become exposed. Statutory monitoring in the UK as required by the Processed Animal Protein Order, 1989, identifies *Salmonella* that may be present in animal (and poultry) feed and subsequently in animal (and poultry) populations.

37.3 COLLATION AND ANALYSIS OF DATA

Following the receipt of reports from microbiologists, primary care and public health physicians, and veterinarians by national, state, or provincial surveillance centers as appropriate, epidemiological data are entered into a database for collation and analysis.

In the UK, data relating to statutorily notified cases of food poisoning in England and Wales are collected and collated by the Office of National Statistics (ONS) in London, in Scotland by the Information and Statistics Division (ISD) of the Common Services Agency of the Scottish Health Service, Edinburgh, and in Northern Ireland (NI) by the Department of Health and Social Security. In addition, the Infectious Diseases Surveillance Systems (IDSS), introduced initially in Wales in 1989 and subsequently in Scotland (SIDSS), are examples of computerized systems collating statutory notification (and other communicable disease) data, enabling rapid analysis of complex data sets, which, in conjunction with Epinet, have made possible the establishment of detailed, up-to-date national databases from health authority computerized data files. The development, for example, of CoSurv in Wales and the French Communicable Diseases Computer Network, further emphasizes the increasing importance of electronically operated databases in collation, analysis, and rapidity of feedback of data, an essential element of surveillance.

Automated statistical scanning of incoming laboratory reports has been developed by the PHLS in England and Wales which, by supplementing routine national surveillance, can facilitate the detection of outbreaks of foodborne disease at an earlier stage than is normally possible.[48]

The EU Salm-Net surveillance system, coordinated at the PHLS Central Public Health Laboratories, London, became operational in early 1994, with the primary aim of strengthening international laboratory-based surveillance relating primarily to incidents of human salmonellosis within the EU by creating an integrated on-line database available to all participating countries. The program, funded by the European Commission, comprises a network of microbiologists and epidemiologists responsible for national surveillance of salmonellosis, thereby facilitating the rapid exchange of information relating to outbreaks or the emergence of specific serotypes or phage types among participating countries. Salm-Net also aims to harmonize across Europe phage-typing schemes for *Salmonella typhimurium*, *S. enteritidis*, *S. virchow*, and *S. dublin*.[51] Since becoming operational, Salm-Net has facilitated the recognition and investigation of multinational outbreaks due to *Salmonella anatum*,[9] *S. agona*,[78] and *S. tosamanga*[64] respectively, as well as outbreaks of *Shigella sonnei*[5] and *E. coli* O157,[7] affecting several European countries. Funding has since been continued under the name of Enter-Net for an additional three years with an expansion of the remit to look at antibiotic resistance in salmonellae and to include VTEC in the surveillance system. Initiatives are under way to extend Enter-Net to become a more global network with the participation of countries in Eastern Europe, Africa, North America, and the Pacific Rim.

In the US, in addition to the development of Food Net, Pulse Net enables public health laboratories using Internet technologies to network with CDC as well as the Department of Agriculture and FDA. It allows public health scientists around the country to compare rapidly the DNA from bacteria involved in outbreaks of foodborne illness, in particular *E. coli* O157:H7.

Global salmonella surveillance is undertaken by the WHO Collaborating Centre based at the Central PHLS Laboratories, London, which collates and analyzes serotype frequencies reported by contributing countries.

37.4 DISSEMINATION OF INFORMATION

One of the essential components of any meaningful surveillance program is the feedback of analyzed data to contributing colleagues (clinicians, microbiologists, public health physicians, EHOs, veterinarians), administrators, and other interested people. This may be in the form of early feedback by telephone, fax, or electronically to alert health authorities as soon as possible of an emerging public health problem, the production and distribution of regular epidemiological bulletins or newsletters, or via published scientific papers.

The production of national (or regional) epidemiological bulletins has now become an important feature in most countries with established surveillance programs, whereby data and other relevant information are collated and published weekly, monthly, or quarterly for distribution nationally and internationally. In the UK, separate reports are produced within England and Wales (*Communicable Disease Report*), Scotland (*Scottish Centre for Infection and Environmental Health Weekly Report*), and Northern Ireland (*Communicable Diseases Monthly Report Northern Ireland*). Similar reports are also published (many in English) in the US (*Morbidity & Mortality Weekly Report*), Canada (*Canada Diseases Weekly Report*), Trinidad & Tobago (*Carec Surveillance Report*), Australia (*Communicable Disease Intelligence*), New Zealand (*New Zealand Public Health Report)*, France (*Bulletin Epidemiologique Hebdomadaire*), Denmark (*Epi-News*), the Netherlands (*Infektieziekten Bulletin*), Germany (*Epidemiologisches Bulletin*), and Spain (*Boletin Epidemiologico Seminal*) at weekly, fortnightly, or monthly intervals. Extracts from national reports are collated by WHO and published (in English and French) in the *Weekly Epidemiological Record*.

The WHO Surveillance Programme for the Control of Foodborne Infections and Intoxications in Europe to date (January 1999) has produced six reports, the first of which was published in 1981, and the most recent in 1995 covering the years 1990–1992,[121] collating and summarizing the data received from each of the participating countries in the European zone. The seventh report is currently being prepared. Periodic newsletters are also produced at more frequent intervals for distribution within collaborating countries.

National reviews summarizing the occurrence of outbreaks or the frequency of isolates of foodborne pathogens are produced (quarterly, annually, periodically) by various countries worldwide, particularly in Europe, North America, and Australasia. Reviews and analyses have also been produced within individual countries relating to specific enteropathogens such as *Salmonella*,[126,128] *Campylobacter*,[119,124,163] *Escherichia coli* O157,[61,154,158] and *Listeria monocytogenes*;[2,92] disease associated with areas of food production including the fish and shellfish[175] and dairy industries;[43,150,151] and hospital,[26,117] cruise ship,[82] airline,[132] and domestic forms of catering.[140] Publications relating to foodborne disease outbreaks and changing trends[41,92,100,127,171] and surveillance programs[121,153] have been produced also.

International publications *EVC News* and *Eurosurveillance* were introduced in Europe in 1996. Of these, the former is specific to VTEC infection and is produced (in English) by the Istituto Superiore di Sanita, Italy, as part of the European VTEC Club

Next Page

(EVC), collecting information on outbreaks, case-clusters, trends, and isolates of unusual strains. *Eurosurveillance*, a monthly publication, is produced (in English and French) by Hôpital National de Saint-Maurice, France, in collaboration with PHLS CDSC, UK, collating data from surveillance networks, reports of outbreak investigations, and other material of international interest within the EU. *Eurosurveillance* is one of several initiatives implementing EU policy, funded by the Directorate General of the EC, to increase the exchange of epidemiological information including the development of surveillance networks along with a training program for field epidemiology in Europe. A further development was the introduction in 1997 of *Eurosurveillance Weekly*, an electronic bulletin (in English) accessible on the World Wide Web or by e-mail, providing brief, authoritative, and up-to-date information on communicable diseases of European significance for public health personnel throughout the EU.

Within individual countries, supplementary epidemiological feedback has been developed by many health authorities (area, regional, provincial) in the form of newsletters circulated to local clinicians, microbiologists, infection control nurses, and EHOs, summarizing outbreaks and other items relating to foodborne (and other) infection of local, national, and international interest.

From October 1997, the EU has been piloting a European electronic network on communicable diseases through the Health Surveillance System for Communicable Disease (HSSCD), a component of the Interchange of Data between Administrations (IDA) program, building on the experience gained in the national surveillance undertaken in individual member states. Following evaluation in a number of countries (eg, Austria, England and Wales, Finland) and when the design is finalized, the network will be extended to other EU countries.[183]

37.5 THE USE OF SURVEILLANCE DATA

37.5.1 The Purpose of Surveillance

The primary role of surveillance is the detection of incidents of disease. Data obtained from surveillance programs, equally importantly, contribute to the longer term measurement of trends and the introduction of intervention or control measures (legislation, health education, media announcements, changes in food production, and processing methods) in the prevention of foodborne (and other) disease.

Surveillance → Information → Intervention → Prevention

Among the many examples of successful intervention following microbiological and epidemiological surveillance were the recognition of outbreaks of infection (salmonellosis, campylobacteriosis) associated with the consumption of raw milk, as a public health problem in Scotland throughout the 1970s and early 1980s.[150] Thereafter, control measures were implemented in 1983 in the form of legislation requiring the heat-treatment of all cow's milk for retail sale to the public[151] and in 1986 requiring that only pasteurized milk be provided to agricultural workers, and not unpasteurized milk as previously, as part of a wage-benefit.[54] Similar national legislation relating to the compulsory heat-treatment of cow's and goat's milk was introduced in Canada in 1991 following outbreaks of salmonellosis and other milkborne infections identified through provincial and federal surveillance programs. Outbreaks associated with the consumption of unpasteurized dairy produce in the UK (including cow's milk in some rural areas of England and Wales), the US, and other countries continue to be reported.[15,24,40,43,60,91]

Outbreaks of milkborne disease have also been reported due to failure to pasteurize properly or to postpasteurization contamination of milk and other dairy products (cheese, powdered milk),[9,10,35,95,111,138,152,154,176] the most extensive of which occurred in Illinois and adjacent states in 1985 affecting more than 16,000 people.[139] The importance of ongoing surveillance in monitoring control measures such as pasteurization and post-pasteurization hygiene at national and processing dairy levels should, therefore, not be minimized.

Surveillance programs also contribute to the recognition of specific epidemiological features of foodborne infection. Considerable differences exist in the incidence of reported disease in relation to the age and geographical distribution of those people affected, in seasonal incidence, and in the types of catering premises associated with outbreaks.

Age Incidence

Foodborne infections affect all ages more or less equally. Nevertheless, the highest reported incidence occurs among young children between 1 to 4 years of age. This age group, together with the elderly, are more likely to (1) have been more seriously ill, (2) have sought medical attention, and (3) have had a fecal (or other) sample submitted for laboratory examination. Infants under 1 year on conventional baby-feeding programs (breast or bottle) generally are less commonly exposed to foodborne disease, although community outbreaks associated with salmonella-contaminated powdered milks have been reported.

Seasonal Incidence

In temperate climates, the incidence of infections due to *Salmonella* and *E. coli* O157 increases noticeably during the summer and early autumn months. Campylobacter infections characteristically peak during late spring and early summer, some 6 to 8 weeks before the "salmonella season," followed in most years by a secondary autumn rise, for which there has been no satisfactory explanation, although ecological and agricultural factors may contribute. Foodborne viral (SRSV, Norwalk-agent) infections, particularly when associated with molluscan shellfish (oysters) farmed in sewage-polluted waters, are reported more frequently over the colder winter months, during which time the depuration (cleansing) process takes longer to be fully effective.

Catering Premises Associated with Outbreaks

Of 1,380 outbreaks of foodborne disease reported in Scotland between 1980 and 1985, 1,012 (73%) occurred as family outbreaks and 368 (27%) as general community outbreaks. The premises where food had been mishandled or contaminated were recorded in 500 outbreaks (36%); of these, commercial catering (hotels, restaurants, cafeterias) was implicated in 180 outbreaks (36%), domestic kitchens in 175 (35%), farms in 43 (9%), and hospitals in 27 (5%). The remaining outbreaks (15%) were associated with various other forms of catering (transport, old persons' homes, oil rigs).[153]

In Europe between 1990 and 1992, the place where food was contaminated or mishandled was reported by relatively few countries (eg, Bulgaria, Israel, the Netherlands, Poland). In 1,375 of 3,172 outbreaks (43%) where data were available, 50% were associated with farms, 22% with restaurants, 13% with private households, and 15% with various other forms of catering.[121]

Geographical Distribution

As a result of the changing and widening patterns of national and international food chains and increasingly mobile populations, many outbreaks of foodborne disease have become more diffuse in their geographical presentation. In addition, the development of the cold chain in food distribution and the widespread availability and use of commercial and domestic refrigerators and deepfreezes may distort the time scale of outbreaks, with cases appearing over a period of several weeks (or months) in different districts, regions, or countries. Furthermore, people affected in the outbreak(s) may have dispersed widely to other areas (or other countries) between eating contaminated food and the onset of illness several hours, days, or weeks later. In consequence, many outbreaks, in particular common-source outbreaks, may remain undetected unless attention is drawn to them via coordinated surveillance of increased reporting of the frequency of an unusual (serotype, phage type) strain.

Rural areas commonly have a higher reported incidence of campylobacter and VTEC than urban areas, reflecting the zoonotic and environmental aspects of many infections.

Contributory Factors

Factors contributing to outbreaks of foodborne disease may not be readily identifiable, particularly after a delay of several days (or longer) between food preparation and the beginning of the epidemiological investigation. In a study in England and Wales in the 1980s analyzing the factors that contributed to the occurrence of 1,479 food poisoning outbreaks, the most important factors reported were the preparation of food too far in advance (57%), storage at ambient temperatures (38%), inadequate cooling (32%), inadequate reheating (26%), eating raw foods (6%), and cross-contamination (6%).[133] In the US the most commonly reported practices that contributed to foodborne outbreaks during 1988 to 1992 were improper holding temperatures followed by poor personal hygiene of food handlers.[127]

Subjectivity on the part of the investigator reporting outbreaks may, however, be misleading, resulting in some factors being over-represented and others under-represented. Although difficult to assess objectively, cross-contamination between raw foods and precooked (or unheated) foods through faulty food hygiene practices (inadequately washed hands, contaminated surfaces, utensils) appears to be a particularly important transmission factor in salmonella and campylobacter infections. The role of infected food workers as the origin of foodborne disease is unclear other than in staphylococcal and some viral infections. In many instances, infected food workers are victims of the outbreak and not the source.

37.5.2 Recognition and Investigation of Outbreaks

Information relating to the occurrence of outbreaks usually is obtained by laboratory (hospital, public health, reference) or physician reporting, from neighboring health departments, and on occasion the media or from individuals affected. The successful investigation of any episode of suspected foodborne disease (outbreak or sporadic case) is facilitated by the physician or laboratory promptly reporting the incident (by telephone, fax, or electronically) to the appropriate health department (Figure 37–3). The flow of information can be further enhanced where a close working relationship exists among laboratory staff, primary care and public health physicians, EHOs, community nurses, and veterinary colleagues, particularly where such relationships have been developed before rather than during an outbreak.

Although in many instances the investigations of outbreaks are successful in identifying food vehicles and etiological agents, and in indicating where control measures should be applied, in other instances the results of investigations are inconclusive. Nevertheless, information thus obtained may provide useful epidemiological data available for subsequent outbreak investigations.

Many cases of foodborne disease occur as sporadic infections and the significance of a single case within the area of an individual physician or local health authority should never be minimized or ignored. In an increasing number of incidents, this could be the first case to be identified in a multidistrict or multistate outbreak, affecting persons widely scattered geographically who had eaten at the same restaurant, attended the same social function, or had eaten contaminated food purchased from different retail outlets (eg, shops, supermarkets) across the country.

Geographically scattered outbreaks are less likely to be detected than locally occurring outbreaks because they are more frequently dependent on subsequent laboratory reporting of specific pathogens, particularly where unusual serotype or phage type strains of *Salmonella* or VTEC have been identified by a reference laboratory. Antibiotic-resistance patterns (antibiograms), DNA fingerprinting, or other identification techniques can also be utilized epidemiologically in the recognition of outbreaks, which were not otherwise apparent.

Routine reports of clusters of acute gastroenteritis in the US in 1993 initiated epidemiological and laboratory investigations in collaboration with the CDC and led to the identification of multistate outbreaks of illness from a Norwalk-like virus associated with eating raw oysters.[46,80] A microbiological and epidemiological study of sporadic cases of listeriosis in the US during 1988 to 1990 demonstrated the presence of *Listeria monocytogenes* in at least one food item from the household refrigerators of 79 of 123 affected persons; of these, one third of the refrigerators contained food(s) that grew *L. monocytogenes* of the same strain as had been isolated from the corresponding patient.[109]

A 5-year review of *E. coli* O157 infection between 1987 and 1991 highlighted the apparent absence of community outbreaks in Alberta, Canada, compared with Scotland, where numerous outbreaks were reported.[182] To what extent such differences were due to the more closely integrated interdisciplinary surveillance program existing within Scotland involving laboratory, public health, and veterinary medicine, supplemented by the accessibility of a dedicated reference laboratory routinely receiving and typing isolates, is not certain.

Routine laboratory surveillance can be used to monitor current trends in the detection of emerging sero/phage types as well as for retrospective analyses. The availability of computer software technology in monitoring epidemiological data can readily detect increases in the number of reports relating to specific sero/phage types over and above normal expected levels.[48]

Following notification or receipt of a laboratory report, a visit is made usually to the home of the affected person by an EHO (or public health nurse) to initiate the epidemiological investigation. This practice may differ widely from country to country, even among health jurisdictions within individual countries, with much depending on national (or local) interests or priorities in investigating reported cases of foodborne disease. In addition to obtaining clinical, epidemiological, and sociological details of the patient (and his or her family), a detailed food history is important, recording what food was eaten (within the home and elsewhere) before the onset of illness by those affected within the relevant incubation period of the reported etiological agent. A good clinical history of the patient's illness is always important and may lead to the likely etiological agent, if not already known. When the predominant presenting symptom is vomiting, as in staphylococcal food poisoning, the incubation period is usually less than 6 hours, but it may be as long as 24 to 36 hours in viral gastroenteritis. If diarrhea is the presenting feature, an incubation period of 8 hours or more is likely.

When the incubation period is particularly short (15 minutes to 1 hour), a toxic or chemical etiology should be considered.

Laboratory investigations need to be undertaken concurrently with the epidemiological inquiries, with the appropriate laboratory alerted as early as possible in the outbreak to enable preparations to be made to deal with the extra workload anticipated. Samples of feces (or other clinical specimens) from cases, suspected foods, and, where available, swabs from kitchen surfaces and utensils (knives, spoons, mixing bowls) should be submitted to the laboratory as soon as possible. Specimens of vomitus are particularly valuable when staphylococcal, *Bacillus cereus*, viral (or chemical) foodborne disease is suspected. Blood samples may also be helpful in the diagnosis of botulism, VTEC infection, and associated HUS.

Assessment of the available clinical, laboratory, and epidemiological findings should help direct the investigation toward a particular meal or item(s) of food. In a point-source outbreak associated with a specific social function, the investigation can be limited to the one (or more) meal(s) common to all those affected. A food-preference study relating to foods that were consumed or were not consumed by those affected can be particularly helpful in pointing toward the contaminated food(s). The study of catering records (or menus) in restaurants, hospitals, and schools may be helpful in pinpointing suspect foods. The location of the food preparation areas and the juxtaposition of cooked foods and uncooked foods (eg, poultry or other raw meats) should be noted specifically, together with storage facilities (eg, refrigeration) and staff food-handling practices. Inquiries should also be made concerning the health (or recent illnesses) experienced by food-handling and catering staff, and the nature of their work in relation to the preparation and serving of implicated food (or meals). This may be particularly important in the investigation of salmonella, shigella, or viral outbreaks.

Other than in point-source outbreaks, it may be difficult to obtain a meaningful food history. Nevertheless, the patient and family should be asked about their regular (and also occasional) eating and shopping habits, with any unusual items noted. Individual food dislikes or dietary restrictions for personal, ethnic, or religious reasons should also be inquired about, enabling certain foods to be excluded from the investigation. In every investigation, it is important to keep an open mind as to the likely food vehicle. Unusual vehicles that have been featured in foodborne outbreaks have included bean sprouts,[102,110] chocolate,[34,59] marshmallows,[85] powdered milk,[9,89,138] salami sticks[31] (salmonellosis); turkey franks,[11,109] pâté,[93,98] coleslaw mix,[146] hot dogs[148] (listeriosis); apple juice,[6,14] fromage frais,[24] fermented sausage,[21] yogurt[97] (VTEC); cheese,[10] yogurt,[101] garlic[142] (botulism); coconut milk[165] (cholera); lettuce[77] (shigellosis); and soft fruits (viral hepatitis A).[8,113]

In the investigation of any outbreak, the cardinal features that should always be noted are:

- ***Time***—When did the illness start? Did all those affected fall ill within a few hours or so of each other, or were they affected over several days or more?
- ***Person***—Who were affected? What common features were present? Were those affected predominantly infants, children attending a day-care center, employees of the same firm, members of the same social club, or a particular ethnic or socio-economically disadvantaged group?
- ***Place***—Where did the incident occur? Was the outbreak associated with a particular hotel or canteen, takeout food from the same restaurant, a wedding party, or other social function?

Plotting an epidemic curve based on the dates of onset of illness of those persons affected in the outbreak should be undertaken. The epidemic curve as exemplified by three different outbreaks of *E. coli* O157 infection (Figures 37–4, 37–5, 37–6) is helpful in giving an indication to the investigator of the type of outbreak being dealt with:

- A ***point-source*** outbreak is associated with a single meal or event involving a specific social or other occasion (eg, wedding meal, christening party, school lunch, golf club outing). In point-source outbreaks, the times (minutes, hours, days, or weeks) of onset of illness (depending on whether the relevant infection has a short or long incubation period) are usually closely clustered together with any subsequent cases due to secondary person-to-person spread appearing later (Figure 37–4).
- A ***common-source*** outbreak involves different groups of persons eating, for example, at the same restaurant or canteen, possibly over a period of several days or associated with eating a contaminated food obtained from the same producer, wholesale, or retail outlet(s) over a period of days, weeks, or months, so that onset of ill-

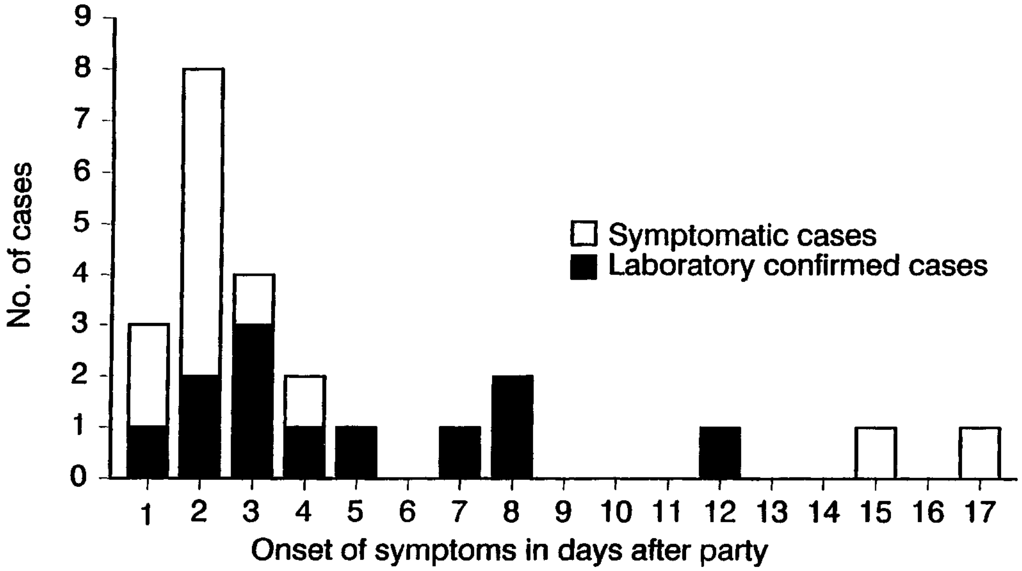

Figure 37–4 Dates of Onset of Illness in a Point-Source Outbreak of *E. coli* O157 Infection Following a Meal at a Party, June 1987. *Source:* Reprinted with the permission of Cambridge University Press from R.L. Salmon et al., A Christening Party Outbreak of Haemorrhagic Colitis and Haemolytic Uraemic Syndrome Associated with *Escherichia coli O157: H7*, *Epidemiology and Infection*, Vol. 103, pp. 249–254, © 1989, Cambridge University Press.

ness dates are more widely distributed (Figure 37–5).

- A ***person-to-person*** outbreak involves subsequent spread occurring in a hospital (nosocomial) or other residential institution or in the wider community, with the distribution of cases compatible with ongoing incubation periods (Figure 37–6).

The shape of the epidemic curve may be affected by variations in the range of the incubation period of the etiological agent responsible or, when occurring in the outside community, by the occurrence of missed (ie, unidentified) cases. In staphylococcal food poisoning, the incubation period may range over a few hours only; in salmonellosis or VTEC infection, it may range over a period of several days, most usually 2 to 3 but possibly longer, and in viral hepatitis over 4 to 6 weeks.

Interpretation of the epidemiological data obtained from the questioning of individual, and possibly numerous, cases in an outbreak investigation can be daunting. In recent years, this has been greatly facilitated by using modern computer programs such as Epi-Info, which can compile and quickly analyze the data.

37.5.3 Analytical Epidemiology

Analytical epidemiological studies such as cohort or case-control studies are frequently undertaken in the investigation of outbreaks, although the possibility of biased results should be guarded against and, where possible, the results should be supported by other (eg, microbiological) data.

Cohort Study

In a cohort study, a comparison is made of the food histories of those people who became ill and those people who remained well, following the consumption of a common meal or after attendance at a social function where food (eg, buffet meal) had been provided. The following are examples of cohort studies.

In the investigation of a point-source outbreak of *E. coli* O157 infection affecting guests at a christening party in England, a food history was taken from affected guests who were microbiologically positive and from others who were unaffected. Food-specific attack rates involving the two groups showed that clinical illness was associated with the consumption of turkey-roll sandwiches ($P < 0.001$), frankfurter sausages ($P < 0.025$), and pork pie ($P < 0.05$). Further analysis of consumption of sandwiches with pork pie or frankfurters demonstrated an independent, stronger association between turkey-roll sandwiches and illness ($P < 0.025$).[144]

An outbreak of cholera affected four people who had attended the same party in Maryland in August 1991 and was associated with the consumption of frozen coconut milk imported from Thailand. Epidemiological and laboratory investigations demon-

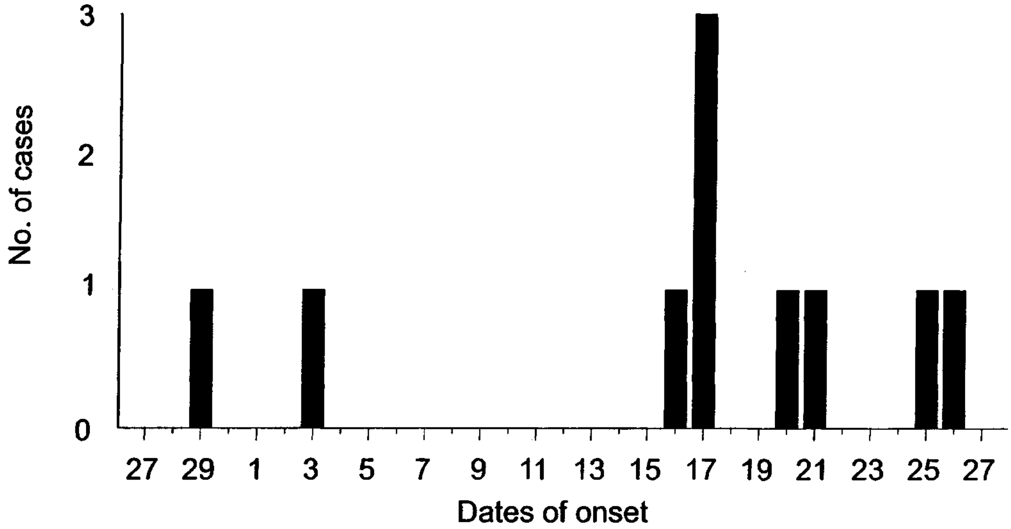

Figure 37–6 Dates of Onset of Illness in an Outbreak of *E. coli* O157 Infection due to Person-to-Person Spread in a Psychiatric Hospital, September-October 1990. *Source:* Adapted with permission from H.S. Kohli et al., A Severe Outbreak of *E. coli* O157 in Two Psychogeriatric Wards, *Journal of Public Health Medicine*, Vol. 16, pp. 11–15, © 1994, Oxford University Press.

strated that infection was associated with attendance at this party (A) and not with a second party (B) held later that same day at the same venue; 4 of 6 people who attended party A had evidence of *Vibrio cholerae* O1 (biotype El Tor, serotype Ogawa) infection compared with 0 of 15 who attended party B (P = 0.003). Subsequent investigation by the FDA resulted in the recovery of *V. cholerae* of the same type from 1 of 6 unopened bags of the same brand of coconut milk as had been consumed by those infected.[165]

Not every analytical study, however, is successful in providing the necessary epidemiological evidence. Following an outbreak of VTEC infection due to *E. coli* O111, in which 10 children developed HUS in northeast France in late 1992, two cohort studies were undertaken comparing the respective food histories of the 10 children who developed HUS with other children who had not developed HUS, and the 10 HUS children and 16 others who had gastroenteritis only with 62 well children at the school attended by the first group of cases. Neither study showed any association between food or water and the occurrence of illness. This, together with the evidence of the epidemic curve with onset of illnesses dates spread over a 14-week period, suggested possible person-to-person spread or spread from a continuing common, possibly food, source.[22]

Cohort studies also can be undertaken on a prospective basis by studying groups of persons (veterinarians, farmworkers, abattoir workers), who potentially are occupationally (or otherwise) exposed to specific enteropathogens.

Case-Control Study

In a case-control study, it is necessary to form an appropriate hypothesis (the null hypothesis) based on the results of earlier descriptive epidemiological findings relating to sociological and other features (eg, eating, shopping, work, or leisure activities) of those people affected that a particular event could not have been a significant factor in causing the outbreak.

In any case-control study, it is important to establish a strict definition of both cases and controls to be included in the study. It usually is necessary to recruit at least two controls (ie, unaffected people who potentially were exposed to the same risk of acquiring infection) for every one case, although in practice this may not always be possible. Controls may be nominated by the case (or parent) in the form of neighborhood controls, from the community health index, from other hospitalized people with an unrelated disease condition or through family physician practice registers, but in each instance controls must be matched with cases as far as possible by age, sex, and social characteristics. Interviewing cases and controls using a prepared, standardized questionnaire may be undertaken either on a face-to-face basis or by telephone, preferably by experienced interviewers. The following are examples showing case-control studies.

In the investigation of a nationwide community outbreak in the UK in 1988 due to *Salmonella typhimurium* definitive type (DT) 124, which had not been apparent as an outbreak at local level, initial epidemiological inquiries suggested that a particular brand of imported salami stick was the likely vehicle of infection. A case-control study showed a statistically significant association between eating imported salami sticks from West Germany and the onset of illness;[31] *S. typhimurium* DT 124 was isolated from a salami stick in an unopened packet obtained from the home of one of the cases interviewed. As a result, the manufacturers withdrew the product from sale.

Following an outbreak of *S. dublin* that affected 42 people in England and Wales in 1989, a case-control study showed a statistically significant association between infection and consumption of soft, unpasteurized cow's milk cheese imported from Ireland. *S. dublin* was subsequently isolated from cheeses obtained from the manufacturer. Control measures included withdrawing the cheese from retail sale, a press release, and a food hazard warning from the Department of Health. The manufacturer subsequently decided to pasteurize milk used in the production of cheese for the UK market.[91]

In September 1994, the Minnesota State Health Department detected an increase in the number of laboratory reports of *S. enteritidis* infection. A case-control study implicated a nationally distributed brand of ice cream associated with the outbreak, following which the product was recalled; *S. enteritidis* was isolated from 8 of 266 ice cream products examined.[65]

Case-control studies have been used on numerous other occasions in incriminating the food vehicle responsible for community outbreaks of other foodborne diseases. Among these were outbreaks of:

- botulism involving chopped garlic in soya bean oil in Canada[142]
- listeriosis involving foods such as brie cheese[60] and pork tongue in jelly[72] in France, Mexican-style cheeses in California,[87] coleslaw mix in Canada,[146] and pâté in the UK[93]
- paratyphoid fever associated with goat's milk cheese in France[40]
- shigellosis in northern Europe associated with imported lettuce from Spain[77]
- staphylococcal food poisoning in the US associated with imported canned mushrooms from China[83]
- VTEC infection associated with hamburgers,[13,36] heat-treated milk,[95,176] vegetables,[96] and yogurt[97] in the US and UK.

Case-control studies can also be used to:

- study emerging community infections, such as those due to *S. virchow* associated with the consumption of poultry meat[185]

- investigate methods of transmission of enteropathogens such as *Campylobacter jejuni*[39]
- study possible disease-associated clinical complications such as the association of campylobacter infection with Guillain-Barré syndrome[112]
- identify risk factors associated with sporadically occurring cases of campylobacteriosis,[1,103] listeriosis,[147] salmonellosis,[31,180] and *E. coli* O157 infection.[145]

Case-control studies are less likely to be successful in the investigation of common-source outbreaks involving commonly eaten foods (eg, poultry meat, hamburgers) than in outbreaks associated with less common foods (eg, salami, cheese), and their power should not be overestimated. Also it is necessary to be aware that analytical studies only identify food(s) consumed by those affected in the outbreaks, whereas the food may have been contaminated from another source (eg, raw meats) during preparation.

37.6 THE ROLE OF REFERENCE LABORATORIES

The contribution of reference laboratories in surveillance and in the recognition and investigation of foodborne outbreaks cannot be overemphasized. Reference laboratories for a wide range of specific foodborne pathogens (*Salmonella, Campylobacter,* VTEC, *Clostridium perfringens, C. botulinum, Staphylococcus aureus, Bacillus cereus, Listeria monocytogenes*) have been established in many countries, in some instances having a primary role as the national surveillance center.

In addition to routine sero- and phage-typing, more definitive epidemiological information has been provided in recent years by the application of newer molecular technologies. These include plasmid profile and DNA fingerprinting studies by pulsed field gel electrophoresis (PFGE) demonstrating correlations, for example, between isolates of enteropathogens from patients and from specific food(s), such as imported poultry.[167] In other instances, discrimination has effectively been made between concurrently occurring foodborne disease incidents, which initially appeared to have been epidemiologically linked. While phage-typing remains a useful tool in routine surveillance and in the preliminary detection of common-source outbreaks, the newer technologies (including PFGE) provide a more definitive discrimination between individual microbiological strains.

The rise in the reported incidence of infection by *Salmonella enteritidis* in Europe (phage type 4) and in North America (phage types 8, 13, and 13a) observed during the 1980s was first detected by national salmonella surveillance programs based on routine phage-typing. Reference laboratory surveillance in the UK during the late 1980s and early 1990s similarly detected the emergence of antibiotic-resistant strains of *S. typhimurium*, in particular phage types 204c, DT 193, and DT 104. In other instances, community outbreaks of foodborne disease (salmonellosis, typhoid, VTEC, listeriosis) due to uncommon sero/phage-type strains have been identified by reference laboratory surveillance and the source of infection traced. Among the many salmonella outbreaks thus detected were those involving nationally or internationally distributed foods such as chocolate (*S. eastbourne, S. napoli*), salami sticks (*S. typhimurium* phage type DT 124), powdered milk (*S. ealing, S. anatum, S. tennessee, S. virchow*), peanut butter (*S. mbandaka*), savory snacks (*S. agona*), bean sprouts (*S. bovismorbificans, S. virchow, S. saint-paul*), cheddar cheese (*S. gold-coast*), goat's milk cheese (*S. paratyphi*), and ethnically prepared poultry-meat (*S. wangata*).

The regular forwarding of isolates of *E. coli* O157 by clinical laboratories to reference laboratories for further characterization similarly has been invaluable in identifying community outbreaks.[37,166] The availability of immunomagnetic separation (IMS) techniques improving the detection of *E. coli* O157 (and other enteropathogens), together with the use of PCR and verotoxin gene-probing from clinical, animal, and food sources, also have facilitated the investigation of outbreaks and the study of apparently unrelated sporadic cases. With the greater use of PCR and genetic probes for the detection of VT genes, it is anticipated that an increasing number of VTEC infections due to non-O157 serogroups will be identified in future years.

The role of reference laboratories in the investigation and control of foodborne diseases of zoonotic origin (eg, salmonellosis, campylobacter, VTEC) is further enhanced where human and veterinary surveillance programs are integrated. Routine typing of isolates of *Salmonella* submitted to the Scottish Salmonella Reference Laboratory indicated a possible epidemiological link implicating the role of seabirds feeding off sewage outfalls in transmitting infection, and a human case of *S. zanzibar* infection in the

Next Page

north of Scotland and subsequent isolates of the same uncommon serotype over a period of several months from (1) milk samples at a nearby dairy farm, (2) "sick" calves at other farms, and (3) abattoir effluents in the same district.[74]

37.7 THE ANALYSIS OF TRENDS AND INTRODUCTION OF CONTROL MEASURES

37.7.1 Trends in Foodborne Disease

Reports of foodborne disease have increased in most westernized countries. Heightened awareness, improved ascertainment, new laboratory technologies, more comprehensive reporting, and enhanced surveillance have undoubtedly contributed to the upward trends observed in recent years. Notifications of food poisoning in the UK, for example, had risen steadily prior to 1982, during which year 17,331 cases (31 per 100,000) were recorded. Thereafter a five-fold rise in notification reports occurred between 1982 and 1994 when 87,692 cases (150 per 100,000) were recorded,[122] in part attributable to the relatively recent inclusion of reports of campylobacter infection in food poisoning statistics. Reports of isolates of *Salmonella*, *Campylobacter*, and *E. coli* O157 increased between 2- and 40-fold over the same period. Similar rises in salmonella isolation rates were observed in other European countries. Campylobacter infections now exceed salmonella infections in Australasia, Canada, and in the UK, and continue to be reported with increasing frequency in continental Europe and in the US where active surveillance has been introduced.[149]

Nevertheless it appears that a real increase in the incidence of foodborne diseases, mainly those (eg, salmonella, campylobacter, VTEC, listeriosis) of animal or environmental origin, has occurred. To what extent this has been due to the many changes that have taken place in food production and processing, such as more intensive farming methods (factory farming), best illustrated by the poultry broiler industry in which tens of thousands of birds are mechanically slaughtered daily within individual processing plants, is not clear. These developments have taken place in parallel with changes in eating habits and other socioeconomic factors, in particular the expansion of mass catering, the greater number of women working outside the home, and the availability of an increasing range of convenience foods.

Conversely, with the exception of viral-associated disease, infections primarily of human origin (eg, shigellosis, typhoid, paratyphoid) that continue to be important public health problems in developing countries are uncommonly transmitted by contaminated food (or water) in westernized countries.

37.7.2 Salmonellosis

The increase in reports of infection due to serotypes (other than *Salmonella typhi* and *S. paratyphi*) has been particularly noticeable in Europe, with most countries reporting a two-fold increase between 1985 and 1992.[121] In the UK, 12,846 infections (23 per 100,000) were reported in 1981 compared with 33,600 (58 per 100,000) in 1994.[122] In North America, lower rates showing little change have been recorded since the early 1980s, particularly in the US, with annual rates varying between 13 and 22 per 100,000. In 1994, 37,506 infections (14 per 100,000) were reported in the US to CDC[126] compared with 7,441 (26 per 100,000) to LCDC.[120]

For many years *S. typhimurium* was the most commonly reported serotype causing human infection. During the mid-1980s, an increased incidence was observed in the frequency of infections due to *S. enteritidis* (in particular phage type 4), which became the predominant serotype in most European and South American countries.[137] In Europe in 1980, fewer than 10% of salmonella infections reported were due to *S. enteritidis*, but by 1992 this figure had increased to more than 50% in some countries and 90% in others.[121] Veterinary surveillance reports in the UK increasingly featured *S. enteritidis* phage type 4 in poultry broiler and egg-laying flocks, concurrent with the upsurge in cases of human infection, which in many instances were associated with eggs and egg products.[32,33,45] Infection due to *S. enteritidis* in Spain had increasingly been associated with egg and egg-based products, such as mayonnaise, since 1978[107] and in the UK in more recent years with eggs imported from other European countries.[38,156] Despite some decrease in reported incidence since 1992, *S. enteritidis* continues to predominate as the most commonly identified serotype in many countries, although not as yet in Australia or New Zealand.

In North America, a marked increase in infections due to *S. enteritidis* (phage types 8, 13, and 13a) was also observed in the later 1980s, initially in northeastern states of the US, associated with outbreaks involving hen eggs,[141] and subsequently in other states and Canada. Outbreaks continue to be associated with the consumption of raw eggs[84] and related products. In 1993 for the first time, eggborne outbreaks due to phage type 4 were reported.[19] Between 1988 (47% of outbreaks) and 1992 (75%), *S. enteritidis* was the most common cause of salmonella outbreaks reported to CDC,[127] and by 1995 had overtaken *S. typhimurium* as the most frequently isolated serotype.

Although now less predominant in many countries, infection by *S. typhimurium* continues to cause considerable human disease. Antibiotic-resistant strains of *S. typhimurium*, in particular phage types 204c, DT 193, and DT 104, have increasingly appeared in recent years in Europe[20,168,180] and North America.[70]

Poultryborne salmonellosis involving a wide range of serotypes continues to be a major feature in most westernized countries, with *S. virchow* and *S. hadar*, for example, also having developed antibiotic resistance in recent years.[56] Irradiation of poultry, the cost-effectiveness of which in controlling salmonellosis has been demonstrated,[189] has been introduced in the Netherlands and in France. Following the introduction of environmental control measures within the poultry broiler industry, however, there are encouraging indications from some countries (eg, UK, Scandinavia) that contamination rates are decreasing.

37.7.3 Campylobacter Enteritis

Since the 1980s, campylobacter (*C. jejuni, C. coli*) infections have exceeded salmonella in their reported incidence in countries with established national surveillance programs (eg, Australia, New Zealand, Canada, the Netherlands, the UK). In New Zealand, for example, national rates of more than 220 per 100,000 have been recorded in recent years, exceeding 300 per 100,000 in some provinces.[130]

In the UK, more than 48,000 cases (84 per 100,000) were reported in 1994[122] with rates exceeding 200 per 100,000 in some areas of Scotland. In 1998, more than 64,400 cases (115 per 100,000) were recorded in the UK. Surveillance studies in the Netherlands have indicated that *Campylobacter* accounts for 15% of acute gastrointestinal disease compared with 5% due to *Salmonella*. Elsewhere in Europe, campylobacter infections continue to be uncommonly reported compared with salmonellosis.[121]

In the US, the extent of under-reporting nationally has been highlighted by active surveillance studies such as FoodNet, which showed that where laboratories in selected areas were routinely screening for *Campylobacter*, isolation rates of up to 71 per 100,000 were recorded[16,124,149] compared with national rates of 5 to 6 per 100,000.[124,163]

The epidemiology of campylobacter infection is considerably less clear than that of salmonellosis. In part this is due to a relative absence of identifiable outbreaks compared with the preponderance of sporadic cases and to the fact that laboratory typing schemes for *Campylobacter* generally have been less available. Consequently, epidemiological investigations often are incomplete, and surveillance programs have been less well developed in most countries.

Despite an increased understanding of the ecology of campylobacters, control measures are relatively difficult to apply within the poultry broiler industry. Cross-infection and cross-contamination are major problems, particularly within rearing farms and processing plants with their high stocking densities, high throughput, and carcass contamination from spilled intestinal contents. Eradication of *Campylobacter* from animal or environmental reservoirs may not be possible, although control measures implemented within poultry farms, such as chlorination of drinking water supplies and the application of specific hygiene measures during the rearing period, have reportedly been successful in reducing the number of organisms present.[106,178] The financial costs to the poultry industry of introducing and maintaining effective preventive measures continue to outweigh market profitability. Irradiation of the finished raw product would be particularly effective as a control measure, but related costs and customer acceptance remain a problem in most countries.

37.7.4 Listeriosis

During the mid-1980s, increases in reports of infection by *Listeria monocytogenes* were observed in several European and North American countries. Extensive foodborne outbreaks associated with unpasteurized soft cheeses and coleslaw mix were reported from Switzerland,[15] the US,[87] and Canada.[146]

In the UK, an increasing number of reports of listeriosis were recorded during the later 1980s, reaching epidemic proportions by 1988 when more than 300 cases were reported, the majority of which were due to two previously uncommonly identified strains (serotypes 4bx and 4b, phage types 6 and 7). These were shown to be indistinguishable by serotyping, phage-typing, and DNA restriction analysis from the isolates recovered from a particular brand of epidemiologically implicated pâté.[93] Control measures and government food warnings in the summer of 1989 relating to pâté consumption by at-risk pregnant women and immunosuppressed individuals were followed by a decline in the number of cases. The incidence of reported infection returned thereafter to the pre-epidemic levels of less than 100 cases that were being recorded annually during the early 1980s.

In France, multiregion community outbreaks were reported in 1992,[72] 1993,[136] and 1995,[60] with microbiological and epidemiological case-control studies identifying pork tongue, pork pâté (rillettes), and raw milk brie cheese, respectively, as the responsible food vehicles. Recall of the incriminated foods in conjunction with improved sanitation and other production control measures resulted in each of the outbreaks being brought under control. In contrast, in 1994 a significant reduction was recorded in the incidence of sporadic cases of infection throughout France that had been attributed to the official recommendations issued to at-risk population groups, in particular pregnant women.[73]

In a 1993 outbreak of gastroenteritis in Italy following a private supper party, *L. monocytogenes* was isolated from blood cultures of 2 of 18 affected people and from various leftover food and kitchen environmental samples, all of which were indistinguishable from the human isolates. Epidemiological investigations identified rice salad as the responsible food vehicle.[143] In July 1994, a similar outbreak of gastroenteritis and fever affected 45 people who had attended a picnic in Illinois. A cohort study demonstrated illness among 45 of 60 people who had consumed chocolate milk (attack rate 75%) at the picnic compared with no illness (0%) among those who did not consume this item; isolates of *L. monocytogenes* from 11 of 45 people affected, from samples of chocolate milk and from a tank drain at the dairy were shown to be indistinguishable from each other.[35]

Active surveillance for sporadic listeriosis in the US was initiated in 1986 based on a widening aggregate population in nine different geographic areas of the country. In 1993, a review of the effectiveness of the intervention control measures introduced (ie, aggressive food monitoring policies, improvements in cleaning, sanitation and control of hygiene during food processing, and issuing advice to vulnerable consumers), showed that these measures were associated with a substantial reduction in the reported incidence of disease in all nine surveillance areas.[161]

37.7.5 Verotoxigenic *Escherichia coli* (VTEC) Infection

Verotoxin-producing *Escherichia coli* (VTEC) or enterohemorrhagic *E. coli* (EHEC) were first described in 1977 in Canada,[81] in which country the highest national rates of infection (mainly *E. coli* O157) were reported throughout the 1980s, increasing from 25 cases in 1982 to a peak of 2,407 (8.9 per 100,000) in 1989. The highest provincial rates (16.0 per 100,000) were recorded in Alberta, where surveillance was particularly active.[182] In 1990, VTEC infection became notifiable throughout Canada. Since then, reported national rates have decreased to 3.5 per 100,000. Following nationwide media attention focused on "hamburger disease" and HUS, intensive health education measures were introduced, supplemented in 1995 by the Canadian Paediatric Society, which issued detailed advice on the importance of high standards of food hygiene and cooking of raw meats.

In the US, although numerous community outbreaks have been recorded since the early 1980s,[61,62,131] very few states (eg, Washington, Oregon, Minnesota) had surveillance programs for *E. coli* O157 infection. As a result, reported national infection rates in the US remained low and trends were less apparent than those observed in Canada. In the extensive West Coast hamburger outbreak in 1993,[13,36] more than 100 cases were recognized belatedly in Nevada, Idaho, and California, states which, unlike Washington, had no surveillance arrangements. In October 1996, a further multistate (California, Colorado, Washington) outbreak with associated cases in British Columbia was reported, in which unpasteurized apple juice was identified as the responsible food vehicle.[6]

National surveillance was formally introduced in the US in 1993 following a recommendation by the Council of State and Territorial Epidemiologists that clinical laboratories begin culturing all stools (bloody and nonbloody) for *E. coli* O157.[30] Within 3 months of enhancing surveillance, a Connecticut laboratory reported the isolation of *E. coli* O157 from four people who were part of a larger outbreak associated with two separate picnics, at both of which hamburgers from the same supplier were served.[135] In 1994 following an increase in case reports, a New Jersey Department of Health survey showed that the number of laboratories culturing all diarrheal specimens for *E. coli* O157 had increased from 2 (10%) to 18 (90%) over the previous 12 months.[50] A later survey in December 1994 of 129 laboratories across the US showed that 38 (29%) were then screening all stools for *E. coli* O157; 32 (25%) screened all bloody stools; and 35 (27%) never screened.[18]

In the UK, an increasing number of cases and outbreaks have been reported since 1990, during which time a greater number of laboratories were extending their screening policies, examining a wider range of fecal specimens other than bloody stools in children. The highest isolation rates have been recorded in Scotland[154] with between 242 (4.7 per 100,000) and 506 (9.9 per 100,000) cases recorded annually during 1994 and 1998. Elsewhere in the UK, isolation rates in England and Wales increased from 0.5 per 100,000 in 1990 to 2.0 per 100,000 in 1997, thereafter decreasing to 1.8 per 100,000 in 1998. Within Wales where active surveillance of *E. coli* O157 has been undertaken since 1990, with all publicly funded laboratories (national health service and PHLS) routinely screening stools from all cases of acute diarrhea,[145] isolation rates of 0.9 to 1.2 per 100,000 were recorded.[122]

In November and December 1996, a major foodborne outbreak associated with meat from a single supplier in central Scotland affected a known 496 cases, of which 272 were laboratory confirmed; 22 elderly people died. *Escherichia coli* O157 organisms of the same type (phage type 2, verotoxin type 2) and PFGE profile, indistinguishable from that of the epidemic strain, were isolated from leftover gravy (meat sauce), from a meal consumed at a church lunch, and from an unopened, vacuum-packed (2.7 kg) packet of cooked meat from the same butcher source.[129]

Whether the incidence of infection outside North America and the UK has been as low as would appear or whether it is the result of differences in ascertainment, in laboratory techniques and policies, or in national surveillance priorities, is not clear. Nevertheless, *E. coli* O157 (and other VTEC) infections have been reported with increasing frequency in recent years from numerous countries worldwide (eg, Australia, Belgium, Denmark, France, Germany, Ireland, Israel, Italy, the Netherlands, New Zealand, South Africa, Spain, Sweden). During 1996 and 1997, extensive foodborne outbreaks of infection due to *E. coli* O157 were reported in Japan; in the largest, several thousand school children and staff were affected.[63] Internationally, the highest rates of HUS have been reported in Argentina,[88] where the disease syndrome has been recognized for many years.

Relatively little is known about the epidemiology of HUS or of infection by VTEC serogroups other than O157. In most instances where non-O157 serogroups were identified, they usually were associated with outbreaks of HUS such as those reported from South Australia,[21] France,[22] and Italy.[23] HUS has been made notifiable in some states in the US and in Australia. Although not notifiable in Europe at present, sentinel surveillance has been established in Austria, France, Italy, and Switzerland. In the UK, HUS was one of several conditions voluntarily reportable during the 1980s to the Surveillance Unit of the Royal College of Paediatrics and Child Health. This arrangement was discontinued in 1988, but restored in 1997 as part of a collaborative active surveillance study of HUS in children involving pediatricians, pediatric nephrologists, microbiologists, and epidemiologists throughout the UK and Ireland.

In April 1997, the WHO convened a consultative meeting on the "Prevention and Control of EHEC Infections" in Geneva, attended by experts from 14 countries to explore the health hazards posed by recent outbreaks. Enhanced investigation and reporting were among the many recommendations adopted at this meeting, with particular emphasis on the establishment of surveillance for HUS whether or not individual countries had the necessary microbiological resources to undertake the surveillance of EHEC (VTEC) infection.[187]

37.7.6 Other Foodborne Infections

Staphylococcal Food Poisoning

Food poisoning due to enterotoxin-producing staphylococci is one of the most commonly reported foodborne diseases internationally, particularly in Latin America,[172] in much of continental Europe,[121] and to a lesser extent in North America.[170] In the UK, although no longer a major cause of foodborne disease compared with the 1950s and 1960s, outbreaks continue to be reported.[184] Incidence and trends are difficult to measure because many cases are unreported unless occurring as a recognizable outbreak.

Overall, the incidence of disease appears to be decreasing in most western European and North American countries, largely as a result of the application of proper temperature control (cooking, chilling, refrigeration) in the preparation of susceptible foods such as in cold buffet-type meals. Elsewhere incidence varies widely in different countries and regions largely dependent on cultural dietary habits and food preparation methods. International outbreaks due to contaminated lasagne imported from Italy[186] and canned mushrooms from China[83] have been reported.

Clostridium perfringens *Food Poisoning*

Food poisoning due to *C. perfringens* is a commonly reported cause of foodborne outbreaks in many European[121] and Latin American countries.[172] Many cases go unreported due to the relatively mild, short-lasting nature of the illness, with epidemiological data restricted to information obtained from the investigation of point-source outbreaks.

Surveillance of *C. perfringens* food poisoning in the UK is coordinated by the PHLS Food Hygiene Laboratory, based on microbiological material from feces and food samples submitted by public health and hospital laboratories. A downward trend in the frequency of reported outbreaks has been observed since the mid-1980s, in particular outbreaks in hospitals and other health care facilities,[26] where a problem existed for many years before the removal in 1987 of immunity of hospital catering from the requirements of UK food hygiene legislation.

Viral Infections

The increase in laboratory reports of viral gastroenteritis has largely been due to the increasing availability of the electron microscope and its use in the investigation of outbreaks. A 40-year review of molluscan shellfish-associated (cockles, mussels, oysters) disease in the UK was published in 1985 and showed a marked increase in reported outbreaks with an established viral etiology (small, round structured viruses [SRSV], hepatitis virus A), many of which were caused by eating raw oysters or inadequately cooked cockles.[155] Similar experiences have been reported in the US[46,80] and in other countries.

Despite education and official health warnings to draw attention to the hazards of eating shellfish harvested in sewage-polluted waters, outbreaks of disease continue to be reported.[90] Viral infections in particular are greatly under-reported, with numerous disease episodes being inconclusively investigated or recognized. Due to the relatively short-lasting clinical effects of most cases of viral gastroenteritis and the 4 to 6 weeks' incubation period of viral hepatitis A, a food (or food-handler) source may not be readily suspected other than in point-source outbreaks associated with a specific meal or social function.[113]

Botulism

Botulism continues to be an important public health problem in much of continental Europe and among indigenous communities in northern regions of Asia and North America. Despite the clinical severity of most cases, the true incidence of disease is difficult to assess. Epidemiological and microbiological confirmation of the food vehicle(s) involved is often unobtainable unless a recognizable outbreak occurs. In some instances, the illness may be uncharacteristically mild and slowly progressive with the diagnosis mistaken for other neurological conditions (eg, Guillain-Barré syndrome, myasthenia gravis, psychiatric disorders, stroke), compounded by instances where those people affected have dispersed over a wide geographic area.[101,142] Infant botulism was first recognized in the US in 1976; since then, cases have been reported periodically from North and South America, Europe, and Australia.[44]

Shigellosis

Although continuing to occur periodically in epidemic form through person-to-person or environmental transmission, most usually affecting young children, shigellosis appears infrequently as a foodborne disease in westernized countries.

In the summer of 1994, several northern European countries—in particular Norway, Sweden, and the UK—reported an increase of *Shigella sonnei* infection mainly affecting adults. Microbiological and epidemiological evidence, including case-control and food preference studies, identified iceberg lettuce of Spanish origin as the responsible food vehicle.[5,77] Among the factors contributing to the termination of the outbreak(s) were (1) the coincidental seasonal changes in the source of supply of lettuce in northern Europe, (2) legislative measures prevailing within Norway prohibiting the import of vegetables when local products become available, and (3) public health warnings relating to the preparation of lettuce and other vegetables to be consumed raw.

Typhoid/Paratyphoid

Foodborne transmission of typhoid and paratyphoid infection has become an uncommon occurrence in westernized countries, with most cases reported presenting as sporadic infections affecting travelers returning from visits to Third World countries. A recent exception was the multiregion outbreak of paratyphoid that affected 273 people in France between August and November 1993, caused by eating contaminated unpasteurized goat's milk cheese.[40]

Foodborne transmission, however, remains a major public health problem in developing countries where drinking water supplies are less likely to be effectively protected from human sewage or where a high proportion of food workers may be chronic excreters of *S. typhi* or *S. paratyphi*.

Yersiniosis

Relatively little is known about the epidemiology of yersiniosis, despite *Yersinia* species having been recognized as a foodborne pathogen since the 1970s. Although outbreaks involving foods such as raw and pasteurized milk products, tofu (soybean curd), and chitterlings (pig intestine) have been reported in some countries, most cases occur as sporadic infections. The true incidence is unknown, with infection most commonly continuing to be reported in countries with a specific research interest (eg, Australia, Belgium, the Netherlands, Denmark, the Baltic states). Few countries other than Australia, Belgium, and Germany have yersiniosis as a notifiable disease.

Pigs are a natural reservoir of infection, with evidence from Belgium[162] and other European countries identifying consumption of raw pork as a significant risk factor.

37.8 CONCLUDING REMARKS

Despite the implementation of a wide range of control measures such as education, food hygiene legislation, and the Hazard Analysis Critical Control Point (HACCP) concept, there appears to have been a real increase in the reported incidence of foodborne disease in recent decades, part of which undoubtedly can be attributed to greater awareness, improved detection methods, and better surveillance systems.

Political, economic, and social changes, in parallel with greater industrialization and intensification of farming, food production, and processing methods and other factors such as changing consumer demands, may have contributed to the on going occurrence of foodborne disease as a worldwide problem. The majority of food manufacturers have now achieved and maintain high standards of hygiene during production, processing, and distribution. Nevertheless, many problems remain, for example, within the poultry-broiler industry with its high throughput of birds. Some anxiety also exists in relation to the production of soft cheeses prepared from unpasteurized milk, in particular by smaller producers, and in relation to those catering businesses that persist in using raw egg in foods conducive to microbial survival and growth.

The basis of any successful surveillance system is to maintain the flow of information and the development of good professional relationships among primary care and public health physicians, microbiologists, epidemiologists, and field workers (EHOs, community nurses). Electronic reporting systems have undoubtedly improved the flow of epidemiological information within and between countries, enhancing surveillance, nationally and internationally. Most modern foodborne diseases are zoonotic in origin, and their surveillance and control require close collaboration with veterinarians and other professional colleagues within the food industry. Geographically scattered community outbreaks are often difficult to detect, especially so in surveillance programs that do not include the expertise of a reference laboratory.

It has been suggested[4] in relation to the multistate hamburger *E. coli* O157 outbreak in the western US in 1993, that despite its magnitude, the public health problem coincidentally prevailing within the states of Nevada, Idaho, and California might not have been recognized, but for the epidemiological link identified in Washington. The outbreak, however, also drew attention to the limitations of the passive surveillance arrangements within Washington, resulting in a delay of some weeks between the occurrence of the first cases and the start of investigations.

Whether or not mandatory reporting systems provide better data than voluntary reporting remains controversial, with circumstances varying from country to country. Cuba, with its comprehensive legislative requirements, has collected national data on foodborne disease more consistently than any other country.[172] Within Europe the highest salmonella isolation rates during the late 1980s and early 1990s were recorded in the former Eastern bloc countries, where mandatory reporting was also a major feature. To what extent these rates were due to more comprehensive reporting or to poorer standards of food hygiene is uncertain. In Western Europe, salmonella surveillance is generally well developed with reporting rates higher than in North America despite the fact that salmonellosis is not formally notifiable in the UK other than as part of the clinical syndrome of "food poisoning" and has been discontinued as a notifiable disease in the Netherlands since 1985. In some countries (eg, the

Netherlands, France), increasing reliance has been placed on data from physician "sentinel" voluntary systems complemented by routine laboratory reporting. Whichever reporting arrangements (mandatory or voluntary) are used, the goodwill and collaboration of all health care workers involved is of paramount importance in providing good quality data.

Syndrome reporting, although providing less definitive epidemiological information than laboratory data, nevertheless has an important role in providing early warning of an emerging outbreak. The reporting by physicians of HUS, for example, even where microbiological confirmation is lacking, nevertheless provides an invaluable indicator of the occurrence of VTEC infection in the community. In future years, clinically based syndrome reporting may become of increasing importance in alerting health authorities, particularly if physicians with financial budgets restrict the number of clinical samples sent for laboratory investigation.

A limiting factor for laboratory-based systems can be the considerable financial costs of routine diagnostic and reference laboratory microbiology, exclusive of the further costs of research and development of new typing and detection techniques. The increasing emphasis currently prevalent in many countries toward financially oriented hospital and primary care health services in parallel with the development of commercially based private laboratories, with consequent reduction in government funding of hospital and public health laboratories, is regrettable and almost certainly will be a retrograde step.

The importance of investigating single cases of foodborne disease, however, should not be underestimated. In France, for example, only outbreaks (and single cases of botulism) are investigated. In many other countries including the UK, some health authorities, due to resource problems, restrict their investigations to formally notified cases or to recognizable outbreaks only. In consequence, important epidemiological data concerning sporadic cases can be lost, not least due to delays in identifying "common-source" community outbreaks. National and international outbreaks usually have small beginnings, often presenting initially as geographically scattered, sporadically occurring cases.

Administrative problems in correlating data obtained from different collection systems (statutory notifications, laboratory reporting, etc.) need not present unacceptable difficulties. Although the correlation of physician notifications with laboratory reports can be readily achieved electronically, linking data between different reporting systems should not be a priority for surveillance. The Communicable Diseases Computer Network in France, based on sentinel physician data on non-notifiable disease conditions, appears to correlate well with formal notification and laboratory-based surveillance systems.

Much still needs to be learned about the ecology and routes of transmission of foodborne zoonotic disease, especially campylobacter, listeria, and VTEC infections. The extent to which these are due to foodborne, waterborne, animal contact, or environmental transmission remains unclear. Little is known about the extent and duration of microbial carriage in food animals (cattle, sheep, etc.). Inter-disciplinary surveillance, allied to collaborative microbiological and epidemiological research, clearly has an important role to play in this area. Surveillance programs for all types of VTEC infection, and in particular HUS, clearly need to be further developed.

It is not clear why the reported rate of *E. coli* O157 infection in Scotland is consistently higher than elsewhere in the UK, or why there should be a disproportionately greater number of outbreaks. It is only since 1994 that laboratories in Scotland have been routinely screening diarrheal feces for *E. coli* O157. Within Scotland regional differences also occur with significantly higher infection rates reported most years by laboratories based in the east of the country than the west.[154] Following the major outbreak of *E. coli* O157 in central Scotland in November and December 1996, wide-reaching recommendations were made by a UK government advisory group emphasizing among other aspects (eg, Research, Enforcement Measures, Outbreak Control) the need for greater priorities to be given to the practicalities, costs and benefits of improvements to the arrangements for surveillance, and data collection and analysis of foodborne disease.[129] In 1998 proposals were placed before parliament for setting up a Food Standards Agency in the UK with far-reaching responsibilities relating to food hygiene and prevention of foodborne disease.[94]

National surveillance programs are as yet insufficiently developed in many countries. In 1997 following the major outbreaks of *E. coli* O157, Japan initiated a nationwide foodborne disease surveillance program with particular emphasis on *Escherichia coli* O157 (and other VTEC serotypes), *Yersinia enterocolitica*, *Campylobacter jejuni* and *C. coli*, *Salmonella enteritidis*, and *Clostridium botulinum* as target organisms. Attention has been drawn to the need to improve surveillance and investigation of foodborne disease internationally.[164,172] Although foodborne disease is recognized by WHO as an important public health problem, the development of surveillance programs has largely been hindered by the lack of political will by many governments, and in consequence deprived of adequate funding.

The need for ongoing analyses of surveillance data, prompt epidemiological investigation, timely communication, close collaboration between epidemiologists and microbiologists, with the importance of advising colleagues in other countries of the distribution of potentially contaminated products at an early stage, cannot be overemphasized. The effectiveness of Salm-Net (now Enter-Net) in Europe is an outstanding example of internationally coordinated surveillance leading to recognition, investigation, and control of foodborne outbreaks.

Foodborne disease is preventable. Microbial contamination levels in raw foods can be reduced significantly by good hygienic practices and the application of effective preventive measures throughout the food chain (eg, by the use of the HACCP concept and the selective use of ionizing irradiation). While the final control measure is dependent on the individual food-handler's (commercial or domestic) understanding of the importance of maintaining high standards of food hygiene in the kitchen, total reliance should not be placed in this area.

Even where effective control measures have been introduced, there may be political pressures to remove them. Milkborne infection, for example, has largely been controlled in countries with legislation requiring the heat-treatment of milk for retail sale, in particular cow's milk. Yet a powerful politically oriented lobby exists in many countries in favor of promoting a market in natural, untreated, organically grown dairy produce.

Routine surveillance, however, cannot always provide definitive scientific evidence implicating specific food vehicles. In addition, the quality of the data on which many programs are based may be open to criticisms such as the inexperience and/or lack of objectivity of approach of investigators, the accuracy and comprehensiveness of their reports, and unseemly delays in the publication of analysis of the data. Surveillance programs, however, have demonstrated their value in providing the epidemiological data necessary for the introduction of intervention measures in the control of foodborne disease. Nevertheless, following the introduction of appropriate control measures, surveillance has to be maintained at a high level in order to monitor their continuing efficacy.

38.1 INTRODUCTION

The *Aeromonas hydrophila* group (motile Aeromonads, mesophilic *Aeromonas*) has presented a challenge to clinical and food microbiologists since the bacterium first was isolated and described as the cause of septicemia in frogs. Although this organism occurs widely in the environment, especially in various water supplies (the name *hydrophila* from the Greek *hydro* and *philos* means water loving)[49,58,66,68] and, as a consequence of contact with water, in many fresh and processed foods, its exact role as a cause of gastroenteritis is still disputed. Its wide occurrence in water and many foods, its ability to grow readily at 5° C (a temperature previously thought adequate to restrict the growth of foodborne pathogens),[98] and the fact that many isolates possess factors associated with virulence suggest that the presence of *A. hydrophila* in foods should be of major concern to food safety microbiologists.[138]

38.2 TAXONOMY AND CHARACTERISTICS

For the early history and background of the bacteria now assigned to the genus *Aeromonas*, see Eddy,[33] Farmer et al.,[35] and Kulp and Borden.[73] Through the years and different editions of Bergey's Manual, bacteria now termed the *A. hydrophila* group were placed in the following genera: *Bacillus*, *Bacterium*, *Aerobacter*, *Proteus*, *Pseudomonas*, *Escherichia*, *Achromobacter*, *Flavobacterium*, *Vibrio*, and *Necromonas*.[35] The *A. hydrophila* group is currently in the family *Vibrionaceae* with the genus *Vibrio*, based on the characteristics of oxidase-positive and motility by polar flagella.[12] Differentiating characteristics of members of the family *Vibrionaceae* are shown in Table 38–1. The family was created to differentiate these organisms from the *Enterobacteriaceae* and no phylogenetic relationships were implied. In 1986, creation of the family *Aeromonadaceae* was proposed[28] based on examination of 16S ribosomal RNA content, 5S RNA sequences, and ribosomal RNA-DNA hybridization data of a large number of isolates. This evidence indicated that *Aeromonas* spp. possess an evolutionary history sufficiently different from the *Vibrio*-

Source: Data from P. Baumann and R.H.W. Schubert, Family *Vibrionaceae Veron* 1965, 5245AL, in *Bergey's Manual of Systematic Bacteriology*, Vol. 1, N.R. Krieg and J.G. Holt, eds., pp. 516–517, © 1984, Williams & Wilkins, and S.W. Joseph and A. Carnahan, The Isolation, Identification, and Systematics of the Motile *Aeromonas* Species, *Annual Review of Fish Disease*, Vol. 4, pp. 315–343, © 1994, Elsevier Applied Science.

naceae to warrant removal from this family. The phylogenetic locus is intermediate between the families *Enterobacteriaceae* and *Vibrionaceae*, and the phylogenetic depth of the genus *Aeromonas* suggests that *Aeromonas* spp. represent a discrete family of eubacteria. This proposed separation is pending.

Organisms in the genus *Aeromonas* are separated generally into two groups based on physiological traits[116] and genetic analyses.[80,117] The genetic analyses indicated that the genus *Aeromonas* consisted of two genotypically legitimate groups, a diverse group of motile aeromonads (designated as species *Aeromonas hydrophila*) and a genetically more homogeneous group of non-motile aeromonads comprising *Aeromonas salmonicida*.

In addition to being non-motile, the *A. salmonicida* group does not grow at 37° C (optimum at 10-15° C) and is sometimes described as psychrophilic. These organisms are found on, and cause disease in, salmid fish. They produce a characteristic brown pigment, especially on media containing tyrosine or phenylalanine.

The motile aeromonads are facultatively anaerobic, Gram-negative rods 1.1 to 4.4 μm long and 0.4 to 1.0 μm wide. Most strains possess polar monotrichous flagella, although some produce short lateral flagella and a few produce lophotrichous flagella. The motile *Aeromonas* species do not produce pigments. Colonies on nutrient agar are translucent to white or buff in color and are round and raised with an entire edge and a smooth surface. The aeromonads are heterotrophic and ferment carbohydrates with production of acid or acid and gas. Biochemically, they are similar to the *Enterobacteriaceae*; however, they can be easily differentiated from the *Enterobacteriaceae* by their ability to produce oxidase. They also produce catalase and reduce nitrates to nitrites. All *Aeromonas* species other than *A. salmonicida* are mesophilic and grow from 4-5° to 42-43° C, with an optimum growth temperature of 28° C. In brain heart infusion broth, the growth range at 28° C is between pH 4.5 and 9.0 and NaCl concentrations of 0% to 4%. Aeromonads are not susceptible to vibriostatic agent 0/129 (2,4-diamino-6,7-diisopropylpteridine).[116]

The classification of the *A. hydrophila* group has been confusing and has changed considerably over time. The introduction of DNA hybridization techniques into bacterial taxonomy allowed bacteria to be classified on the basis of their genetic relationships. After genetic relationships are established and bacterial groups separated, bacterial taxonomists then locate phenotypic traits to permit the routine differentiation of genotypes. Such is the case with the *A. hydrophila* group.

At present, there are 14 recognized DNA hybridization groups (HGs) of *Aeromonas*, which comprise 14 genospecies and 10 phenospecies, with 4 unnamed.[56] A scheme has been developed based on nine biochemical tests and two antibiotic sensitivities that will allow separation of the currently known HGs (Table 38–2). Because the scheme has been developed only recently, most isolates from food have been reported and described as *A. hydrophila* group, motile *Aeromonas*, or have been classified by the older biochemical scheme of Popoff et al.[117] as *A. hydrophila, A. sobria,* and/or *A. caviae.*

Two recent food surveys have classified isolates beyond these three species. In the first, using an expanded biochemical scheme, *A. schubertii* was identified from Brazilian white cheese.[136] In the second, using DNA hybridization techniques, *A. jandaei* and *A. veronii* biotype *sobria* were identified in addition to these three species.[152]

38.3 EPIDEMIOLOGY AND CHARACTERISTICS OF THE DISEASE

The role of the *A. hydrophila* group as a disease agent has been recognized since its initial isolation as the cause of red leg disease in frogs.[124] It remains an important cause of disease in fish.[8] In humans, *Aeromonas* spp. are associated with two distinct disease syndromes: septicemia and various tissue infections (*A. veronii* subsp. sobria and *A. hydrophila*)[54,85] and gastroenteritis (any mesophilic *Aeromonas* spp. but principally *A. hydrophila* and *A. veronii*).[85]

Although the one feeding study of *Aeromonas* failed to demonstrate diarrhea in human volunteers[89] and there is currently not a suitable animal model for diarrhea, a compelling argument can be developed to support the notion that the mesophilic *Aeromonas* group can cause human gastroenteritis (a less rigorous argument for the consideration of *A. hydrophila* as an enteric pathogen was presented by Ljungh and Wadstrom in 1985[78]).

The following facts indicate that *Aeromonas* spp. may be a cause of gastroenteritis in humans:

- Food isolates of the *A. hydrophila* group possess various factors associated with virulence in other enteric pathogens including various enterotoxins, hemolysins, proteases, hemagglutinins, and endotoxins.[1,94,97,104,119,120]
- The *A. hydrophila* group is isolated with greater frequency as the sole pathogen from certain individuals with diarrhea than other enteric pathogens.[3,37,40,49] This increased frequency was observed in children[3,40] and adults.[37] The three groups of investigators[3,37,49] noted a seasonal variation, with higher isolation rates seen during the warmer summer months. Hazen et al.[47] observed higher *Aeromonas* levels in water during the warmer summer months, suggesting a link to human illness; higher levels in water could lead to a greater chance of contamination of food or the possibility that water itself is the vehicle for these bacteria.
- *A. hydrophila* has been isolated as the sole or primary pathogen from food implicated in outbreaks of gastroenteritis.[2,5,67] In the first, Abeyta et al.[2] isolated *A. hydrophila* from oysters associated with a large foodborne disease outbreak. The bacterium was positive in the suckling mouse test and the Adrenal Y-1 mouse test, expressed hemolysin, and showed activity in the rabbit ileal loop (RIL). The isolates came from oysters that had been frozen for 1½ years, and there were no patient isolates available for comparison. In the second, *A. hydrophila* with identical biochemical and ribosomal RNA gene restriction patterns was isolated from both the patient with diarrhea and the leftover food.[5] The last outbreak was associated with a shrimp salad. *A. hydrophila* was detected in salad samples at levels ranging from 10^6 to $>10^7$ cfu g^{-1} of food. Other common foodborne pathogens were either absent or detected at low levels. The isolates from this study produced the following virulence-associated factors: β-hemolysin, cytotoxins, cytotonic toxins, and enterotoxins and they adhered to and invaded Henle 407 cells.[67]
- The *A. hydrophila* group is associated with infections in patients immunocompromised by treatment for various malignancies.[32,45,135] These infections include both systemic bacteremias[32,45] and diarrhea.[135] In retrospective patient interviews, Sherlock et al.[135] determined that their patients had no recent contact with water or fish, suggesting that their gastrointestinal tract was the likely source of the bacterium.

- Serological evidence can provide further support for the causal relationship of the *A. hydrophila* group to diarrhea. Based on very few patients, neutralizing antibodies to various exotoxins (hemolysin, enterotoxin, and cytolysin) produced by the patients' isolates have been detected in patients' sera.[22,43,70] The significance of these observations is not known, especially since the report of Gurwith et al.[43] in which the maximum titer was detected about 2 months after the diarrhea ceased. This area, like many others in *A. hydrophila* research, awaits further clarification.

Patients with *Aeromonas*-associated gastroenteritis can present with several types of diarrhea. These include (listed in decreasing frequency): secretory, dysenteric, chronic, choleraic, and Travelers'.[54] The different types of diarrhea likely reflect virulence factors expressed by the different strains isolated from these cases of gastroenteritis. For example, Gracey et al.[40] indicated that their isolates produced enterotoxins and their patients presented with secretory-type diarrhea.

38.4 MECHANISMS OF PATHOGENICITY

Bacteria of the *A. hydrophila* group produce a wide range of factors associated with virulence in other bacteria.[17,54] These include structural components and extracellular (exotoxins) and cell-associated factors. Structural components, identified in various isolates of the *A. hydrophila* group, that may be related to virulence include pili, S-layer (the major virulence factor in *A. salmonicida*), lipopolysaccharides, outer membrane proteins, and flagella.[53] There has been, however, little research that demonstrates a relationship between these components and virulence in this group of bacteria. Data from the literature suggest that the various exotoxins most likely represent significant virulence factors in these bacteria. Bacteria of the *A. hydrophila* group produce a wide range of extracellular products including hemolysins (aerolysin), enterotoxins, a cholera-toxin cross reactive factor, a cytotonic enterotoxin, proteases, and siderophores. Cell-associated factors that may be related to virulence in these bacteria are invasins, serum resistance, and adherence factor(s).

Stelma et al.[142] proposed that the major, if not sole, virulence factor in *A. hydrophila* was β-hemolysin. They observed that β-hemolysin correlated with fluid accumulation in the RIL assay (used to detect enterotoxin). Palumbo,[101] in reviewing the literature on the formation of putative virulence factors by food and water isolates of the *A. hydrophila* group, observed that, based on 12 published studies, most isolates formed a series of factors including β-hemolysin. Strains of *A. hydrophila* and *A. sobria* produced enterotoxin (detected by the suckling mouse test) and hemolysin (rabbit red blood cells) in a meat extract broth held at both 12 and 5° C.[82] Temperature can influence the expression of various virulence-associated factors and, in many instances, there was greater expression at lower incubation temperatures.[100]

Most of the research concerning *Aeromonas* pathogenicity has focused on the putative enterotoxins produced by diarrheagenic strains. Despite the fact that this research has been ongoing for over a decade, little is known about the roles of these toxins in human diarrhea. Furthermore, information on the number and nature of the *Aeromonas* enterotoxins is both confusing and controversial. Investigators who have found evidence for one type of enterotoxin frequently have failed to find any evidence for the others.

The first reported *A. hydrophila* enterotoxin was a cytonic enterotoxin, similar to cholera toxin with respect to its activities, which included causing fluid accumulation in the RIL, rounding of Y-1 adrenal cells without death, and elevation of cyclic AMP levels in Y-1 cells. The purified toxin had a molecular weight of 15,000, was heat-stable at 56° C for 20 minutes, and was not serologically related to cholera toxin (CT).[76,77,79] Two hemolysins (alpha and beta) were purified, neither of which had enterotoxic activities in animal models.[78,80] Further evidence for a heat-stable *Aeromonas* cytotonic enterotoxin was obtained when the gene for *A. hydrophila* cytotonic enterotoxin was cloned into *E. coli.* The clone produced an enterotoxin that caused elongation of Chinese hamster ovary (CHO) cells and fluid accumulation in the RIL. Both of these activities were heat-stable at 56° C for 20 minutes, and neither activity was neutralized by antiserum produced against CT.[21]

Several other reports provide evidence for *Aeromonas* cytotonic enterotoxins, some quite different from the one described originally. These include: (1) a heat-stable (56° C, 20 minutes) cytotonic enterotoxin that cross-reacted serologically with CT and had biological activities, including causing fluid accumulation in the RIL, that were neutralized by anti-CT;[118] (2) a similar toxin that caused elevation of cAMP levels in CHO cells but was only partially neutralized by anti-CT;[131] and (3) a cytotonic enterotoxin with a molecular weight of 44,000 that was heat-labile at 56° C, free of hemolytic and cytoxic activities, and not cross-reactive with antiserum to CT.[23] The purified toxin caused fluid accumulation in the RIL, elongation of CHO cells, and elevation of cAMP levels in CHO cells. Recently another[84] novel cytotonic toxin with no homology to any other known microbial toxin was purified. This toxin caused fluid accumulation in infant mice and CHO cell elongation but did not elevate levels of cAMP in CHO cells. CHO cell activity was not neutralized by anti-CT.

Preliminary evidence for production of a cytotoxic enterotoxin by *Aeromonas* spp. was provided by several studies in which enterotoxin production was correlated with cytotoxic activity, ie, rounding and death of tissue culture cells. Cumberbatch et al.[31] correlated cytotoxic and RIL activities; all of their cytotoxic isolates were also hemolytic. Turnbull et al.[146] and Burke et al.[15] also noted strong correlations between enterotoxin production and hemolytic activity.

Asao et al.[6] provided the first direct evidence for a cytotoxic *A. hydrophila* enterotoxin when they purified a hemolysin from *A. hydrophila* strain AH-1 to electrophoretic homogeneity and showed that it caused fluid accumulation in the RIL and in suckling mice and was cytotoxic to Vero cells. The purified hemolysin had a molecular weight of 50,000 and was heat-labile at 56° C. The purified hemolysin from AH-1 was shown to be a β hemolysin, and antiserum to the purified hemolysin completely neutralized the RIL activities of filtrates of β-hemolytic *Aeromonas* isolates, indicating that the hemolysin alone can cause the changes in intestinal permeability associated with diarrhea. A polyclonal antiserum against purified AH-1 hemolysin cross-reacted with hemolysins produced by *Aeromonas* isolates from diverse geographic origins.[142] Several studies provided evidence that the *Aeromonas* β-hemolysins are a family of molecules related to the "aerolysin" originally described by Bernheimer and Avigad[13] and that these toxins occurred across species. The hemolysin produced by an *A. hydrophila* isolate (CA-11) from a United States (US) gulf coast oyster was immunologically related to the hemolysin produced by the Japanese strain, AH-1.[7] The CA-11 hemolysin also possessed unique antigenic determinants, indicating that the two toxins are related but not identical. Hemolysins from *A. sobria* and *A. veronii* were shown also to have enterotoxic activities and to be serologically related to AH-1 hemolysin.[24,66,86,143] Rose et al.[122,123] purified a 52,000 molecular weight protein that was hemolytic, cytotoxic, and caused fluid accumulation in the RIL. Their toxin cross-reacted with CT as well as with AH-1 hemolysin, but none of the toxin's biological activities were neutralized by anti-CT. Later studies showed that the CT cross-reactivity was due to small stretches of amino acid similarity between the two toxins and that there were also some homologous sequences with *Clostridium perfringens* A-toxin and listeriolysin.[25]

The results of several surveys suggest either that the cytotoxic enterotoxins are the most common *Aeromonas* enterotoxins or that their activities are higher than, or mask, those of the other toxins. Seidler et al.[133] found cytotonic activity in the filtrates of only 20 of 330 isolates, and Stelma et al.[142] found cytotonic activity in only 1 of 24 filtrates. Cumberbatch et al.[31] observed no cytotonic activity in the filtrates of 96 isolates, and Johnson and Lior[55] found no cytotonic activity in the filtrates of 73 isolates.

Some of the conflicting data generated in early studies, including the inability of researchers working with one toxin to detect the others, are becoming understandable as more studies are performed. Ljungh et al.[76,79] reported that purified β-hemolysin was not active in the RIL. This may have been due to the purification method they used. Their six-step procedure resulted in the recovery of only 0.6% of the original hemolytic activity; whereas the two-step procedure of Asao et al.[6] resulted in the recovery of 65% of the original hemolytic activity and probably yielded a product closer to the native molecule in all its properties. There may be separate loci on the hemolysin molecule for different biological activities, with the hemolysins produced by some isolates having the enterotoxic site masked.[25] This would explain the absence of a perfect correlation between hemolysin production and enterotoxigenicity among *Aeromonas* isolates, as well as the lack of RIL activity in the hemolysin purified by Ljungh et al.[76,79] The failure of many investigators to observe the activity of heat-stable cytonic enterotoxins could be due to insufficient amounts in crude filtrates of many isolates. This possibility was shown by Chopra et al.,[26] who cloned a heat-stable enterotoxin gene into *Escherichia coli* from an *Aeromonas* isolate that produced toxin levels too low to allow detection in culture filtrates. The inability of many researchers to detect the various heat-labile cytotonic enterotoxins is due probably to interference by the cytotoxins.

A. caviae is isolated usually from diarrheal stools of very young children or elderly adults.[4,60,70,72,91] The symptoms associated with *A. caviae* are reported to be less acute than those associated with *A. hydrophila* or *A. sobria*.[72] *A. caviae* generally is considered to have low pathogenic potential and to be nonenterotoxigenic. In one survey, 95% of 284 *A. caviae* isolates were nonhemolytic.[88] In other surveys, only 2 of 284 *A. caviae* isolates were enterotoxigenic, as measured by the suckling mouse test,[6] and only one cytotoxic and no hemolytic strains were found among 106 stool isolates.[71] Only one report provides evidence for a possible enterotoxin. Like earlier investigators, Namdari and Bottone[91] were unable to detect enterotoxin in filtrates of *A. caviae* grown in single-strength tryptic soy broth (TSB). However, when they grew the same isolates in double-strength TSB, they detected a heat-stable cytotoxin that also was enterotoxic, as demonstrated by the suckling mouse assay.

The mostly negative results in a human feeding study suggest that factors other than enterotoxin are important in *Aeromonas* enteropathogenicity. Fifty-seven volunteers were given five known RIL-positive enterotoxigenic strains, but only two volunteers developed diarrhea. These strains were not invasive, and it was hypothesized that they also lacked the necessary adhesion factors to colonize the intestine.[89] This hypothesis was supported by an earlier study showing that both enterotoxins and adhesins were necessary to produce diarrhea in volunteers fed orally with enterotoxigenic *E. coli*[129] and by later studies showing that few strains of *A. hydrophila* and *A. sobria* possess adhesions.[93]

Although the adherence properties of the motile aeromonads are not well characterized, some important information has been acquired. Aggregative adherence, similar to that of enteroadherent-aggregative *E. coli*, was observed in *A. hydrophila* and *A. sobria*. In contrast, *A. caviae* showed a diffuse adherence pattern.[92] Attachment to adrenal cells was correlated with the presence of pili and with specific *Aeromonas* spp.[27] Hydrophobicity and the ability to autoagglutinate did not correlate. *A. sobria*, *A. hydrophila*, and *A. veronii* showed a greater ability to attach than did *A. caviae*. Hokama et al.[48] described two types of pili on an *A. hydrophila* isolate, one rigid and straight (R-pili) and the other wavy and flexible (W-pili, fimbriae). Purified W-pili blocked adherence of the organisms to rabbit intestines, suggesting that the W-pili are a colonization factor. Thornley et al.[145] observed that clinical strains of *A. caviae* adhered to two human cell lines to varying degrees and noted a correlation between adherence and both piliation and hemagglutination. Nishikawa et al.[93] showed by electron microscopy that strains of *Aeromonas* spp. did not possess fimbriae, but these strains could invade Caco-2 cells. They concluded that these strains of *Aeromonas* spp. adhered to and invaded tissue culture cells by a mechanism that remained to be elucidated. One of the most interesting observations was that environmental enterotoxigenic isolates possessed numerous pili that were lost when infection was established, suggesting that environmental isolates may be more infective than clinical isolates.[63]

Another interesting observation was a negative correlation between adherence and the presence of an R-plasmid.[44] Some *Aeromonas* strains are capable of invading mammalian cells. In one study, 18 of 69 (26%) fecal isolates were able to invade HEp-2 cells; 13 of these strains were also enterotoxigenic. A relationship between invasiveness and biotype was noted also; 16 of the invasive strains were *A. sobria*, two were *A. hydrophila*, and none were *A. caviae*. The investigators suggested that the invasive strains produced dysenteric symptoms.[150] Another study demonstrated that some *Aeromonas* strains invaded the intestinal mucosa of rabbits.[115] The invasiveness of *A. caviae* was investigated using criteria developed earlier for *Campylobacter*. The results agreed with those of previous investigations in that the majority of *A. caviae* strains showed little or no invasive ability. However, 8% of the strains were invasive in HEp-2 cells and 25% were invasive in the more sensitive Caco-2 cell model.[134]

38.5 INCIDENCE OF THE BACTERIA IN THE ENVIRONMENT AND FOODS

As indicated in the Introduction, the *A. hydrophila* group occurs widely in the aquatic environment and its presence in food likely reflects contact of contaminated water with the various food products. The results of some incidence surveys of different water supplies are shown in Table 38–3. The reported incidence varied from detection in 33% of samples in one municipal supply to two instances with 100% incidence. The levels encountered range from 0.01 cfu ml^{-1} (the low limit of detection) up to 9×10^3 cfu ml^{-1}.

Bacteria of the *A. hydrophila* group possess two traits that aid aquatic bacteria in their contamination of food products: their ability to survive for long periods in various types of water[106] and their ability to grow in the presence of low levels of organic compounds.[106,147]

The isolation of bacteria of the *A. hydrophila* group from chlorinated drinking water[16] suggests

Table 38–3 Incidence of Members of the *A. hydrophila* Group in Different Water Supplies.

*Ah** indicates biochemical testing not done to speciate isolates beyond the *A. hydrophila* group.

that these bacteria may be resistant to the levels of residual chlorine found in potable (drinking) water. However, Knochel[64] demonstrated that *A. hydrophila* was more chlorine-sensitive than coliform and other indicator bacteria and that any level of chlorine that inactivated coliforms would also inactivate *A. hydrophila*. The presence of *A. hydrophila* in properly chlorinated water may be explained by a high organic content, which would react with the residual chlorine, or by the presence of the bacterium in a protective biofilm inside the distribution system or recontamination by the *A. hydrophila* group.

The *A. hydrophila* group has been isolated from virtually every type of food, including fish (Table 38–4), dairy products (Table 38–5), poultry (Table 38–6), red meats (Table 38–7), and miscellaneous foods (Table 38–8). Water is the likely source of these bacteria in most foods, especially because animal feces contain only low levels of them. The levels encountered in foods vary widely, from <10^{2} CFU g^{-1} to 10^{7} CFU g^{-1}. The counts listed in Tables 38–4 to 38–8 are for the products at the time of purchase. However, at least two groups of investigators[18,108] observed that *A. hydrophila* counts increase with time even if the food is refrigerated (5° C). The presence of these bacteria in heated foods (pasteurized milk and ice cream, Table 38–5; ham, cooked tripe, and smoked cooked sausages, Table 38–8) likely reflects contamination of these foods after the heating step.

38.6 FACTORS AFFECTING SURVIVAL AND GROWTH, PARTICULARLY IN FOODS

38.6.1 Temperature

Most strains of *A. hydrophila* tested grew in culture broth over the temperature range of 4-5° C to 42° C.[109] *A. hydrophila* will grow in a variety of fresh foods stored at 5° C, including red meat and poultry, shell- and finfish, vegetables, and milk.[18,108,121] The bacterium not only grew at this temperature, but grew in the presence of the background flora of the food. Palumbo et al.[108] observed that *A. hydrophila* comprised 10% of the bacterial count of a poultry sample. The minimum growth temperature prob-

ably approaches the freezing point of individual foods; growth occurred in culture at 1° C[33] and at 0° C in purge (drip) from a lamb carcass.[41]

According to Popoff,[116] the optimum temperature for growth of the mesophilic aeromonads is 28° C. Palumbo[102] observed the same lag time at 28° C and 37° C (Table 38–9), with a shortest generation time at 28° C for one strain. A comparison of lag and generation times for 24 clinical and environmental isolates at 29° or 37° C showed that many strains had shorter lag times at one temperature and shorter generation times at the other.[140] The maximum growth temperature for most strains of *A. hydrophila* appears to be at least 42° C,[109] with most enterotoxigenic strains capable of growth at 43° C.[62]

38.6.2 Salt and Water Activity

Palumbo et al.[109] conducted one of the first comprehensive studies of the effect of salt on the growth of *A. hydrophila*. The highest level of NaCl that would allow growth was a function of pH and temperature. At 28° C, many *A. hydrophila* strains grew in the presence of 4.5% NaCl and pH 7.3; as the temperature decreased, the growth-limiting NaCl level also decreased. NaCl restricts growth of microorganisms by lowering the water activity (see Chapter 7). The minimum a_w that supported growth of three strains of *A. hydrophila* varied with temperature and humectant.[126] Growth was limited at higher a_w when NaCl was used than when polyethylene glycol was used to lower the a_w; the effect of glycerol was intermediate.

Table 38–9 Effect of Temperature on the Growth of *A. hydrophila* K144 in BHI Broth[102]*

Temperature ° C	*Generation Time (h)***	*Lag Time (h)***
42	1.21 ± 0.21	32.44 ± 5.57
37	0.53 ± 0.01	2.54 ± 0.76
28	0.40 ± 0.01	2.56 ± 0.15
19	0.86 ± 0.03	7.06 ± 0.46
12	1.52 ± 0.06	15.15 ± 2.21
5	3.62 ± 0.08	43.84 ± 0.85

*The inoculum was grown with shaking (200 rpm) overnight to early stationary phase (18 hr) in BHI broth at 28°C, diluted in 0.1% peptone broth, and inoculated into 50 ml quantities of BHI broth in 250 ml flasks to yield a starting count of *ca* 10^3 CFU ml^{-1}. Triplicate flasks were placed at each of the temperatures, shaken at 200 rpm, and sampled at appropriate intervals. Viable cell counts were performed by surface plating (with a Spiral Plater) onto duplicate tryptic soy agar plates, and colonies were counted after 24–36 hrs at 28° C. Growth kinetics were calculated using the Gompertz equation in conjunction with Abacus, a nonlinear iterative regression program.

**Average of triplicate flasks ± standard deviation.

38.6.3 pH and Acidulant

The acid tolerance of strains is a function of both temperature and NaCl content of the growth medium.[109] At 28° C, 3 of 10 strains grew at pH 4.5 in medium acidified with HCl (within 3 days), while at 5° C, only 4 of 10 strains grew at pH 5.5 (within 13 to 17 days), and none grew at pH 4.5. The limiting pH of *A. hydrophila* was a function of different acidulants, with HCl being the most permissive.[110] The inhibitory activity of acids appeared to be related to their pK_as and followed the order from least inhibitory to most: HCl<H_2SO_4<tartaric<citric<lactic<acetic. Despite the apparent sensitivity of *A. hydrophila* to acetic acid in a culture system, the bacterium has been isolated from salads prepared with mayonnaise;[65] the pH of these foods averaged 5.8, which is borderline inhibitory for *A. hydrophila*[110] depending on salt level and storage temperature. It is not known whether the bacterium was present as a contaminant or some increase in numbers had occurred. When inoculated into pasteurized milk used for the manufacture of yogurt, *A. hydrophila* died off during storage of the product held at 4° C after fermentation.[9,10]

38.6.4 Nitrite

Inhibition of bacterial growth by nitrite is pH-dependent, with little or no inhibition at pH 6.0 or above, and, in general, nitrite is a much more effective inhibitor under anaerobic conditions.[20] The responses of *A. hydrophila* to nitrite are similar to those of other bacteria: maximum inhibitory activity is at pH 6.0 and below and maximum activity occurs under anaerobic conditions.[112,113] The isolation of the *A. hydrophila* group from cooked, sliced ham and mettwurst in product surveys[39] undoubtedly reflects post-processing contamination rather than growth in the product. The residual nitrite in most cured meat products is extremely low and probably has little inhibitory effect.

38.6.5 Gaseous Atmosphere

The *A. hydrophila* group is facultatively anaerobic.[116] These bacteria have been isolated from various anaerobically (vacuum) and modified atmosphere-packaged refrigerated fresh meats.[14,34,38,74,90,132,136] The background flora that develops during storage often has a greater controlling influence than atmosphere or even temperature.

38.6.6 Chemical Preservatives

Various compounds added directly or indirectly to foods can inhibit the growth of *A. hydrophila*. These include essential oils, liquid smoke, food preservatives, and polyphosphates. *A. hydrophila* was inhibited by the essential oils of clove, coriander, nutmeg, and pepper tested in both a model system and a noncured cooked pork.[141] The bacterium was inhibited by liquid smoke isolated from several species of wood.[139] *A. hydrophila* was the most sensitive of four psychrotrophic foodborne bacteria studied to the food preservatives methyl p-hydroxybenzoate and potassium sorbate.[87] *A. hydrophila* was sensitive to the food preservatives butylated hydroxyanisole, propylhydroxy parabenzoate, and sodium tripolyphosphate; protease secretion was more sensitive than growth.[148] Palumbo et al.[105] studied the effect of food polyphosphates (Sodaphos, Hexaphos, sodium pyrophosphate, and sodium tripolyphosphate) on the growth of the bacterium in both a model system and ground pork. In a culture broth, the polyphosphates caused small changes in lag and generation times; however, when polyphosphates were combined with 3.5% NaCl, the number of viable *A. hydrophila* declined. In contrast, most of the other compounds mentioned above simply inhibit the growth of *A. hydrophila* but may be useful when combined with other factors such as increased NaCl or lowered pH. Additional studies are needed to increase the effectiveness of compounds already used in foods.

38.6.7 Combination of Preservative Factors

Predictive modeling studies (see Chapter 16) have been made of the effect of combinations of temperature, pH, NaCl, nitrite, and atmosphere on *A. hydrophila*.[112,113]

38.6.8 Bacteriocins

Several lactic acid bacteria (LAB) cultures showed activity against *A. hydrophila* in a culture broth.[75] The bacteriocin(s) of a lactic starter inhibited *A. hydrophila* in both skim and ewe's milk.[127] Neither nisin (4000 activity units ml^{-1}) nor pediocin (4000 activity units ml^{-1}) alone was effective against *A. hydrophila*, but when combined with a preliminary heating or freezing treatment, the bacterium became sensitive.[57]

38.6.9 Heating

The heat resistance of *A. hydrophila*, as of other bacteria, is influenced by factors such as growth temperature, age of the culture, and heating menstruum (food or buffer).[29,111] The relatively few studies on the resistance/sensitivity of *A. hydrophila* to heat suggest that treatments such as milk pasteurization and frankfurter processing (heating to a final processing temperature of 160° F) should inactivate levels encountered in most raw foods. *A. hydrophila* was more heat sensitive than *Salmonella typhimurium* and *Escherichia coli* O157:H7 when heated in either hamburger or egg yolk.[95] Condon et al.[29] determined a $D_{55^\circ C} = 0.17$ min and a $z = 5.11^\circ$ C for single strain heated in buffer. Palumbo et al.[112] studied five strains (three clinical and two food isolates) heated in saline and raw milk and observed $D_{48^\circ C}$ of 5.2 and 4.3 min respectively and a $z = 6.21^\circ$ C.

38.6.10 Irradiation

Radiation *D*-values at 2° C of five strains of the bacterium in ground beef and blue fish ranged from 0.14 to 0.19 kGy.[107] This is similar to most other Gram-negative bacteria associated with food (see Chapter 4). Thus, any irradiation treatment given to a food to eliminate other Gram-negative pathogens should also eliminate *A. hydrophila*.

38.6.11 Chlorine and Disinfectants

Chlorine represents one of the major food processing plant disinfectants and the major, if not sole, disinfectant used in the final stage of water treatment in the US. Overall, *A. hydrophila* is more susceptible to chlorination than *E. coli*;[64] however, *A. hydrophila* can be isolated from chlorinated drinking water[16] as well as from water with a negative coliform test. Though there are several potential explanations, high organic content of the water may react with the chlorine and thus result in inadequate chlorination and inadequate destruction of the bacterium.[130]

38.6.12 Lactoperoxidase (LP) System

The LP system is effective against both Gram-positive and Gram-negative bacteria. Recent work by Santos et al.[125,127] indicated the potential of using the LP system to inactivate *A. hydrophila* (starting count 10^2-10^3 ml^{-1} or g^{-1}) in culture broth, skim and ewe's milk, and in a ewe's milk soft cheese. The LP system was effective also against the spoilage flora of these products, making it useful to extend product shelf life and protect against this pathogen.

38.7 PRINCIPLES OF DETECTION AND ISOLATION

38.7.1 General Considerations

Members of the *A. hydrophila* group can be isolated easily using most general, all-purpose bacteriological media and on various specific and differential media. On a nonselective medium such as tryptic soy agar, they are difficult to distinguish morphologically from members of the *Enterobacteriaceae*. Also, on differential media such as MacConkey agar, the *A. hydrophila* group resembles other non-aeromonads and may appear as lactose-positive or lactose-negative. The oxidase test is used generally to distinguish these bacteria from other closely related bacteria. The organism can be isolated readily from food and environmental and clinical specimens. Because mesophilic aeromonads can proliferate at refrigeration temperatures, immediate analysis of samples in the laboratory is preferred. If samples are to be analyzed within a day or two, they should be stored at refrigeration temperatures. Samples kept longer should be stored at –20° C or –72° C. Survival of mesophilic aeromonads at frozen temperatures has not been studied; however, Abeyta et al.[2] recovered *A. hydrophila* from oysters held frozen for 1.5 years at –72° C. An enrichment technique may be necessary when analyzing frozen foods, or foods that may contain injured bacteria, for the presence of mesophilic aeromonads.

38.7.2 Procedures and Sampling

Specific details on sample preparation and general isolation procedures are described elsewhere.[103]

An enrichment step is indicated if low numbers of mesophilic *A. hydrophila* group are anticipated or if the cells may have become injured, eg by heating or freezing. Two enrichment broths used successfully for the *A. hydrophila* group are alkaline peptone water (APW) and tryptic soy broth + ampicillin (TSBP). Although no studies comparing their effectiveness have been done, each appears adequate to recover the *A. hydrophila* group from foods. APW has been used for foods such as lamb,[81] ice cream,[51] and mixed seafoods;[151] while TSBP has been used for frozen oysters[2] and raw and pasteurized milk.[61] These four groups of investigators either did not determine the total bacterial count or it was low (1.1×10^3 cfu g^{-1}) so no comment can be made on how well these two enrichment broths perform in isolating the *A. hydrophila* group from foods with high total bacterial counts.

After enrichment and sample preparation, an aliquot of the food is plated onto a medium selective for the *A. hydrophila* group. The current plating medium of choice for food samples appears to be starch ampicillin agar (SAA).[108] SAA contains ampicillin at 10 µg ml^{-1} to suppress Gram-negative background organisms and starch as the differential substance (members of the *A. hydrophila* group are among the few amylase-positive bacteria in foods). SAA was developed in 1985 and has found widespread acceptance for the isolation of the *A. hydrophila* group from food. Various recovery media for the *A. hydrophila* group have been evaluated by comparing both quantitative recovery of these bacteria and ease of distinguishing *A. hydrophila* from other bacteria.[63,137,144] For example, 85% of presumptive *Aeromonas* colonies on SAA were confirmed, compared with much lower percentages on three other recovery media.[63] Singh[137] observed a higher recovery rate of the *A. hydrophila* group on SAA than on two other recovery media. Numerous workers have used SAA to recover these bacteria from milk, meats, vegetables, fish, and processed foods.[18,50,61,65,96,108,137]

However, some strains of the *A. hydrophila* group have been reported to be sensitive to ampicillin,[118] and other plating media may be needed to recover these bacteria. Several media have been used with clinical specimens.[149] Members of the *A. hydrophila* group are sensitive to bile salts, and thus any bile salts–containing media would yield a lower quantitative recovery.[15,108] Any prospective plating medium should be evaluated carefully to ensure both quantitative recovery of members of the *A. hydrophila* group and ease of distinguishing these bacteria from the background microflora.

Any isolate can be identified easily as belonging to the *A. hydrophila* group by using a simple single-tube medium[59] that combines seven biochemical reactions in the one tube. This medium offers good differentiation of *A. hydrophila* from the biochemically similar enterics. After performing the oxidase test, the following additional reactions will verify the identity of isolates: Gram-negative rods 0.3-1.0 µm × 1.0-3.5 µm, motile by a single polar flagellum, metabolism of glucose is both respiratory and fermentative (carbohydrates broken down to acid or acid and gas), and resistance to the vibriostatic agent at the 150 μg level.[116] See Table 38–1 for further distinguishing characteristics. Speciation of isolates is performed using appropriate biochemical tests (Table 38–2); this scheme allows identification of all currently known HGs. Because it is often not feasible to perform all the tests in Table 38–2, investigators have developed rapid identification schemes. These are based on a limited number of biochemical tests and appear particularly useful in the clinical laboratory.[1,19] A scheme based on 9 to 16 tests allowed 99% of the strains to be assigned to the correct HG.[1] Aerokey II, a simpler scheme of 7 tests (esculin hydrolysis, gas from glucose, acid from arabinose, indole production, acid from sucrose, Voges-Proskauer, and resistance to cephalothin [30 μg]), was proposed by Carnahan et al.[19] and permitted them to identify correctly 97% of the strains tested.

Rapid identification kits are available and have been compared for their ability to confirm *Aeromonas* isolates.[96] Of API 20E, API 20NE, and Microbact 24E, API 20NE and Microbact 24E correctly identified 96.3% of the food isolates studied.

38.8 CONTROL

Food microbiologists generally rely on the three "Ks" to control the incidence and level of undesirable microorganisms (pathogens and spoilage agents) in foods: keep them out of the food, keep them from growing in the food, and kill them. These principles are applied to control the incidence and level of the *A. hydrophila* group in foods. The widespread occurrence of the *A. hydrophila* group in various foods (Tables 38–4 to 38–8) at a high incidence although low levels suggests that it is difficult to keep them out of most foods. However, their low levels would suggest that food conditions (salt concentrations and pH and acid type combined with low holding temperatures) can restrict their increase. The source of these bacteria in foods may be contaminated water (Table 38–3) and/or animal feces.[42,144] However, because of their low incidence and level in animal feces,[42,144] water is probably the main source of these bacteria in foods.

The importance of water as a potential vehicle for these bacteria was suggested further by the demonstration that depending on holding temperature, organic content, and residual chlorine, *A. hydrophila* could remain viable for several weeks in various water supplies and even increase in number.[106]

It is difficult to prevent members of the *A. hydrophila* group from growing in most fresh foods, even when the foods are adequately refrigerated (5° C).[11,18,108] Although they have been detected in various cooked, cured, and fermented foods, their incidence and level tends to be low.[39,50,65] Some exceptions are known, however. For example, 10^7 CFU *A. hydrophila* g^{-1} were detected in cooked tripe, suggesting either gross contamination and/or gross temperature abuse of the product after cooking.[152]

Survey data[39,50,65,108] suggest that although members of the *A. hydrophila* group appear to be sensitive to the salt and pH (acid) content of foods, they will survive conditions found in fresh foods. Palumbo et al.[108] did not observe any increase in *A. hydrophila* in fresh pork sausage (salt level, *ca* 2%) over one week's storage at 5° C. In culture, *A. hydrophila* is sensitive to pH values of 5.5 and below, especially if the pH is adjusted with lactic or acetic acids.[110] The number of viable *A. hydrophila* decreased in ground pork when conditions favored growth and acid production by LAB.[100]

A. hydrophila has been detected in vacuum- and modified atmosphere–packaged meats. Because members of this group are facultative anaerobes, this is not unexpected. The fate of *A. hydrophila* in these meat products appears to depend on the competing microflora that develop. As indicated above, the numbers of viable *A. hydrophila* in ground pork decreased as developing LAB produced lactic acid.[99] Raw shucked oysters were one of the few fresh foods in which the numbers of *A. hydrophila* decreased during refrigerated storage. LAB developed during storage and converted carbohydrates present in the oysters to lactic acid and thus inactivated the *A. hydrophila* present.[108]

The presence of the *A. hydrophila* group in foods can be controlled by heating, irradiation, chlorine, disinfectants, and the LP system (see Sections 38.6.9 to 38.6.12) which inactivate or kill the bacterium. Control by pH and acidulant (See Section 38.6.3) is multifactorial, with factors such as NaCl level, temperature, and acidulant playing important roles. With regard to pH and acidulant, these bacteria are often inhibited rather than killed.

38.9 CONCLUDING REMARKS

The *A. hydrophila* group represents a challenge and enigma to both clinical and food microbiologists. *A. hydrophila* is a recognized cause of systemic infections in immunocompetent individuals and can cause specific problems in immunocompromised patients. The bacteria are recognized pathogens of fish. These bacteria occur widely in both aquatic and food environments where they often can reach fairly high numbers, even in foods properly refrigerated. Isolates form factors that are associated with virulence in other pathogens, and clinical isolates possess these same virulence-associated factors. Circumstantial evidence points to a role for these bacteria as agents of diarrheal disease even though conclusive epidemiological evidence is lacking. There is not a current animal model, and the one human volunteer feeding study gave inclusive results.

There are many areas where more information is needed to relate members of the *A. hydrophila* group and diarrheal disease. One suggested approach would include a detailed molecular epidemiological comparison of clinical and food and water isolates from the same geographic area and the same time period to determine the source of the patients' strains. A foodborne disease outbreak in which the isolate from food exactly matches the patient isolate would provide a further link between *A. hydrophila* group and diarrheal disease. Havelaar et al.[46] compared diarrheal and water isolates using three typing methods (biotyping, serotyping, and gas-liquid chromatography of cell wall fatty acid methyl esters). They found little overall similarity between diarrheal and water isolates and concluded that environmental (water) strains that can infect humans are rare and probably represent a special subset of those occurring in water.

Clinical isolates should be investigated for new and different virulence factors and mechanisms. Although research on the *A. hydrophila* group lacks the urgency of that on recognized pathogens, the potential exists for this group to become a major problem, considering its wide occurrence in the environment and its ability to grow at refrigeration temperatures. It is tempting to speculate that the *A. hydrophila* group is responsible for at least a portion of foodborne disease outbreaks of unknown etiology.

39 *Bacillus* species

Per Einer Granum and Tony C. Baird-Parker

39.1 Introduction
39.2 Taxonomy and typing of the food poisoning *Bacillus* species
39.3 Characteristics of human disease
39.4 Epidemiology
39.5 Mechanisms of disease
  39.5.1 The emetic syndrome
  39.5.2 The diarrheal syndrome
  39.5.3 Other *Bacillus* species
39.6 Incidence in the environment and in foods
39.7 Growth, survival, and destruction in foods
39.8 Detection and enumeration
  39.8.1 Enumeration of the organism

39.1 INTRODUCTION

Bacillus cereus is a common soil saprophyte. It has been isolated from a wide variety of foods, especially of plant origin, but also from meat, fish, and dairy products.[42] It was first recognized as a foodborne pathogen in 1949, when Hauge[33,34] isolated this species from vanilla sauce following an outbreak of diarrheal food poisoning at a hospital in Oslo, Norway. The vanilla sauce was cooked the day before consumption and stored at room temperature until served. To demonstrate that *B. cereus* was the cause of illness, Hauge grew the isolated organism to a concentration of about 4×10^6 ml^{-1} and drank 200 ml of the cocktail. After 13 hours he developed abdominal pain and watery diarrhea; these symptoms persisted for about 8 hours.[34] More than 20 years later another form of *B. cereus* food poisoning was described by workers in England.[46] The symptoms were dominated by vomiting and a short incubation period (<5 h), indicating that this was an intoxication.[46] This disease is now referred to as *B. cereus* Emetic Syndrome.

During the last decade, psychrotrophic strains of *B. cereus* have been recognized that are able to grow at 4 to 6° C.[18,28,32,66,69] These organisms are potentially of concern in pasteurized milk and preprepared chill-stored meals. Also there have been a number of reports of food poisoning caused by four other *Bacillus* species: *B. thuringiensis, B. subtilis, B. licheniformis*, and *B. pumilis*.[41,42] Most strains of *B. thuringiensis* produce the same enterotoxins as *B. cereus*, but nothing has been reported concerning the virulence factors of the other species (Damgaard and Granum, unpublished).

39.2 TAXONOMY AND TYPING OF THE FOOD POISONING *BACILLUS* SPECIES

The genus *Bacillus* is taxonomically complex. The most studied *Bacillus* species belong to the mesophilic group with growth temperature optima between 30° and 45° C, while members of the thermophilic group may grow at temperatures as high as 65° C but often fail to grow below 45° C. All the food poisoning *Bacillus* spp. belong to the mesophilic group, which is further divided into three groups;[17,51] all the food poisoning strains belong to Group 1. This group is composed of Gram-positive species forming ellipsoidal or cylindrical spores, usually without distended sporangia; most species within this group will grow both aerobically and anaerobically. It is further divided into Group 1A and 1B

The authors wish to thank Dr R.J. Gilbert for providing additional material for this chapter.

based on vegetative cell dimensions and the presence of lipid globules in the cytoplasm. Group 1A consists of species with cell widths >0.9 μm, producing lipid globules and includes *B. cereus*, *B. megaterium*, *B. thuringiensis*, *B. mycoides*, and *B. anthracis*. Group 1B contains species with cell widths <0.9 μm and without lipid globules, and includes *B. subtilis*, *B. licheniformis*, *B. pumilis*, and *B. coagulans*. This grouping of *Bacillus* spp. is taxonomically not satisfactory, and only DNA studies will reveal the true relationship of the species. Indeed, some studies already have suggested that *B. cereus*, *B. megaterium*, *B. thuringiensis*, *B. mycoides*, and *B. anthracis* should be considered subspecies of the same species.[7,8,14,18] In the laboratory, however, it is useful to distinguish these species, which can be done using the characteristics listed in Table 39–1.

A serotyping scheme based on flagellar antigens has been developed for *B. cereus*;[62] 42 serotypes currently are recognized. Certain serotypes are more commonly involved in the emetic food poisoning–type (serotypes 1, 3, and 8) and others with the diarrheal type (serotypes 1, 2, 6, 8, 10, and 19).[22,42] Serotype 1 is most commonly involved in food poisoning worldwide but most serotypes have been implicated.[42] There are no known genetic relationships between *B. cereus* virulence factors and flagella antigens; such a relationship is unlikely. Consequently, serotyping is not particularly useful for identifying food poisoning strains. Phage typing,[4] plasmid analysis,[48] random amplified polymorphic DNA (RAPD)[59] and polymerase chain reaction (AP-PCR)[45] are useful for subtyping strains from food poisoning incidents.

39.3 CHARACTERISTICS OF HUMAN DISEASE

Bacillus cereus may cause many different infections and intoxications.[42] In addition to foodborne diseases, *B. cereus* causes septicemia, meningitis, and ocular infections.[19,42] The two types of food poisoning are caused by very different virulence factors. The emetic disease, characterized by a short incubation period (1 to 5 hours) is caused by a small cyclic polypeptide (cereulide)[3] preformed in certain foods (eg, rice). The symptoms include nausea, vomiting, and stomach cramps (Table 39–2). The diarrheal disease is characterized by an incubation period of 8 to 16 hours with symptoms including abdominal pain, watery diarrhea, and rectal tenesmus (Table 39–3). It is caused by the production of enterotoxin(s) during the vegetative growth of *B. cereus* in the small intestine following the ingestion of bacterial cells or spores.[24,29] Usually both types of food poisoning are relatively mild, lasting for less than 24 hours, and do not usually require medical attention. However, occasionally a more severe type of diarrhea may occur, which may be caused by colonization of the epithelial cells of the small intestine by *B. cereus* spores, followed by outgrowth and enterotoxin production.[5]

Food poisoning caused by *B. subtilis*, *B. licheniformis*, and *B. pumilis* is similar to that caused by *B. cereus* in duration and range of symptoms. However, the incubation period and symptoms vary between and within species (Table 39–7). *Bacillus thuringiensis* is believed to produce the same enterotoxin as *B. cereus*, but nothing is known about the food poisoning toxins of the other three *Bacillus* species.

39.4 EPIDEMIOLOGY

Since *B. cereus* food poisoning is not a reportable disease, the true incidence of illness is unknown. It was reported to be the cause of 33% of cases of food poisoning (excluding those caused by viruses) in Norway (1988–1993);[25] 47% in Iceland (1985–1992); 22% in Finland (1992); 8.5% in the Netherlands (1991); and 5% in Denmark (1990–1992).[55] Much lower figures have been reported from other countries including the United States (US) (1.3%) and Canada (2.2%).[42] In England and Wales, there were 63 outbreaks (468 cases) from 1990 to 1995; over the same period, there were 65 outbreaks and 4,474 cases in Japan (R. Gilbert personal communication, 1997). Many fewer cases of food poisoning involving other *Bacillus* spp. have been reported, but 180 incidents involving more than 900 cases were reported in the United Kingdom (UK) between 1974 and 1996

Table 39–1 Criteria To Differentiate between the Four Closely Related *Bacillus* Species

Species	*Colony Morphology Blood Agar*	*Hemolysis*	*Motility*	*Susceptible to Penicillin*	*Parasporal Crystal Inclusion*

Table 39–2 Characteristics of the Emetic Disease and Properties of the Emetic Toxin from *Bacillus cereus*

Property/Activity	*Description*
Intoxication dose	Number of *B. cereus*: 10^5 to 10^8 cells per gram food Amount of toxin: 12–32 μg kg^{-1} (*Suncus murinus:* a small monkey)
Toxin produced	In foods (25 to 35° C) as a secondary metabolite (?)
Incubation period	½ to 5 h
Duration of the illness	6 to 24 h
Symptoms	Nausea, vomiting (sometimes followed by diarrhea, due to additional enterotoxin production?)
Most frequently implicated foods	Fried and cooked rice, pasta, and noodles
Name of toxin	Cereulide
Structure of toxin	Cyclic peptide: $[\text{D-O-Leu-D-Ala-L-O-Val-L-Val}]_3$
Molecular mass	1.2 kDa
Isoelectric point	Uncharged
Antigenicity	None
Biological activity on man	Emesis
Type of receptor	5-HT_3 (binding stimulates the vagus afferent nerve)
Result of ileal loop tests	None
Cytotoxic	No
Activity on HEp-2 cells	Vacuolation activity
Heat stability	90 min at 121° C (no loss of activity)
Effect of proteolysis	None
How is the toxin produced	Not known, but probably enzymatically

(Table 39–4); mainly *B. subtilis* and *B. licheniformis* are involved. The types of foods and illnesses involved in *B. cereus* food poisoning in different parts of the world reflect eating habits (Table 39–5). Thus, in rice-eating countries such as Japan, India, Korea, and Thailand, the emetic type of poisoning is most common. In Europe and North America, the diarrheal type is most common and involves vegetable and meat-based foods.[42] Although milk commonly is contaminated with *B. cereus* spores and toxin may form,[15] it is seldom involved in *B. cereus* food poisoning. The reason for this is believed to be that insufficient growth occurs before spoilage is apparent.[43]

39.5 MECHANISMS OF DISEASE

39.5.1 The Emetic Syndrome

The characteristics of disease and the properties of the emetic toxin are summarized in Table 39–2. The elucidation of the emetic toxin structure has led to new insights into this syndrome. The emetic toxin

Table 39–3 Characteristics of the Diarrheal Disease Caused by *Bacillus cereus*

	Property
Infective dose	Usual 10^5 g^{-1} or ml^{-1}
Toxin produced	In the small intestine of the host
Type of toxin	Protein
Incubation period	8 to 16 h (occasionally >24 h)
Duration of illness	12 to 24 h (occasionally several days)
Symptoms	Abdominal pain, watery diarrhea, sometimes with nausea
Most frequently implicated foods	Meat products, soups, vegetables, puddings/sauces, and milk/milk products

has been named cereulide and is a cyclic peptide of three repeats of four amino-and/or oxy-acids (Table 39–2). The ring structure (dodecadepsipeptide) has a molecular mass of 1.2 kDa and is chemically closely related to the potassium ionophore valinomycin.[1,3] The biosynthetic pathway of the emetic toxin has yet to be elucidated, but its mode of action seems to be through stimulation of the vagus afferent nerve by binding of the 5-HT$_3$ receptor.[3] It is not clear whether the toxin is a modified gene product or is produced enzymatically in the cell or through modification of components of the growth medium. However, with such a structure, it is most likely that cereulide is an enzymatically synthesized peptide and not a gene product.

Previously it was believed that the emetic toxin was a lipid structure[24,42,57] because of its hydrophobic nature. Because of the structure of the emetic toxin, it is not surprising that it is not antigenic and is resistant to heat, pH, and proteolysis (Table 39–2). It is possible that other emetic toxins may exist, and these may be closely related structures.

Table 39–4 *Bacillus* Species Associated with Food Poisoning in England and Wales, 1974–1996

Species Implicated	*Incidents*	*Cases*

39.5.2 The Diarrheal Syndrome

The diarrheal syndrome is caused by at least two enterotoxins produced during vegetative growth of *B. cereus* in the small intestine.[24,29] Formation of sufficient enterotoxin in the food to cause food poisoning is theoretically possible, but such food would usually not be acceptable for human consumption. For this to occur, the numbers of *B. cereus* present in the food must be at least 10^6 g^{-1} or ml^{-1},[16,42] and sufficiently high amounts of enterotoxin must be formed to survive the pH of the stomach and the proteolytic enzymes of the duodenum.[24,29] These factors will rapidly reduce the enterotoxin activity to less than 1% of the initial level.[24,29] The relatively long time between the ingestion of the organism and occurrence of disease symptoms also supports the view that *preformed* enterotoxin is unlikely to be a factor in this syndrome.

The characteristics of the diarrheal syndrome are summarized in Table 39–3. The variation in the infective dose may be due to the ability of different strains to produce enterotoxin(s) and to the different susceptibility of individuals.

In Norway, two outbreaks have occurred in which many people were affected after eating stew (meat, potatoes, and vegetables). The infective dose was approximately 10^4 to 10^5. In the first outbreak (1992), 17 of 24 people exposed were affected and three of the patients were hospitalized, one for three

weeks;[5,23] the onset of symptoms was late (>24 h) in these three patients. The second outbreak was in February 1995 when 152 of 252 people were affected during the Norwegian junior ski championships.[27] The young competitors (16 to 19 years of age) suffered severe symptoms, while their coaches and the officials were not affected at all. Some of the skiers became ill after an incubation period of more than 24 hours and were ill for from one to several days.

The *B. cereus* spores from the first outbreak described above are distinctive in that they have the ability to adhere to Caco-2 cells (human intestinal epithelial cells).[5] After adhesion, the spores quickly germinate (within 1 hour), forming a vegetative *B. cereus* cell monolayer on top of the epithelial cells, followed by *in situ* production of enterotoxin. If this occurred in the intestinal tract, the enterotoxin concentration localized in the periphery of the tract would be much higher than in the lumen and thus cause greater damage to the tract and greater severity of disease. One would expect that with such a mechanism, the incubation period would be longer, as was observed. The local defense mechanisms would then determine the severity of the disease. The three people hospitalized in the first outbreak were over 50 years old and, in the second, only the young athletes were ill. It is likely that athletes in intense training are under stress and are perhaps more susceptible to intestinal infections.

The number and types of enterotoxins involved in the diarrheal form of *B. cereus* food poisoning have been the subject of debate for many years and remain controversial.[10,12,24,42,50,63,64] Both single- and multicomponent enterotoxins have been suggested to be the cause of illness.[2,12,24,31,42,44,56,63] Two different three-component enterotoxins are produced by food poisoning strains of *B. cereus.*[12,35,44,63] Several groups also have also described single-component enterotoxins with molecular weights of about 40 to 100 kDa.[12,20,24,31,42,63,64] However, the activities of these latter proteins may be due to contamination with traces of other proteins. The current knowledge of *B. cereus* enterotoxins is summarized in Table 39–6.

The early studies on enterotoxins[42,64] suggested that either a single-component or multicomponent toxin was involved. Further studies supported the hypothesis of a multicomponent toxin,[63] and a three-component hemolysin with enterotoxin activity was purified and characterized.[9,10,12] Although good evidence was presented that all three components were necessary for maximal enterotoxin activity,[12] other workers[31,55] have continued to claim that a one-component enterotoxin is responsible for all the activity. Since similar purification procedures were used by these two groups, it is tempting to suggest that they purified the same protein. By sequencing (Table 39–6), it has been shown that the protein purified by Granum and Nissen[31] is identical to the B component (37.8 kDa protein) of the hemolysin HBL purified by previous workers.[9,10,12,35] Since the B component and the L_1 component (38.2 kDa protein) have similar molecular weights, it is quite possible that the protein (B component) purified by the two groups was contaminated with the L_1 component. It is, however, more difficult to understand a possible contamination with the L_2 component. Until all these proteins can be expressed separately (after cloning), it is difficult to reach any conclusions on

Table 39–6 Properties of Enterotoxins Isolated from *Bacillus cereus*

Enterotoxin/Reference	*Molecular Weight*	*N-Terminal Sequence*	*Biological Test Used*	*DNA Sequenced*	*Hemolytic*
One main protein and two other protein components[42,64]	50 kDa	ND[1]	Positive on: rabbit loop tests, vascular permeability tests, and mouse lethality tests	No	Yes

how many components must be present for biological activity. Given that only a very few molecules of an additional component can result in biological activity, nothing can be ruled out on the structure and cooperation of the components of this enterotoxin. However, further support for three component enterotoxins was recently provided by Lund and Granum,[44] who purified three other components as part of a nonhemolytic enterotoxin. Two of these proteins are close in molecular weight to that observed for the HBL enterotoxin (Table 39–6), but have different N-terminal sequences. The third protein is much larger (105 kDa) and may possibly be the same as the protein purified by Ezepchuk et al.[20] Interestingly, none of these three proteins cross-react with the L_2 component.

Some strains of *B. cereus* produce two enterotoxins, while other strains produce only one,[26] but we do not know the distribution of the two enterotoxin complexes among strains or how important each is in relation to food poisoning. It is possible that at least some of the components of the two enterotoxins may substitute for each other and still remain enterotoxic. There is some sequence similarity between the L_1 component and the 39 kDa protein purified by Lund and Granum.[44]

Enterotoxin T is a single-component enterotoxin that has never been shown to cause food poisoning.[2] The enterotoxin T gene recently was shown to be absent in 57 of 95 strains of *B. cereus* and in 5 of 7 strains involved in food poisoning.[26]

39.5.3 Other *Bacillus* Species

Bacillus cereus and *B. thuringiensis* food poisoning is caused by the same types of enterotoxin(s). Nothing is known of the virulence factors (toxins) involved in the three other *Bacillus* spp. that are reported to cause food poisoning; the little that is known about these types of food poisoning is summarized in Table 39–7. The incubation period and symptoms vary among and within species. This may be indicative of more than one virulence factor, as the described symptoms indicate both emetic and diarrheal toxins may be involved.

39.6 INCIDENCE IN THE ENVIRONMENT AND IN FOODS

Spores and vegetative cells of *B. cereus* and the other food poisoning *Bacillus* spp. occur widely in soils (soil has been shown to contain 10^5 to 10^6 spores g^{-1}) and may be found in virtually all raw and processed foods with the exception of those sterilized by heat or irradiation. In a comprehensive study of the occurrence of *B. cereus* in foodstuffs, Nygren[49] examined 3,888 food materials, finding contamination rates of 51.6% in food ingredients, 44% in milk and dairy products, and 52.1% in meat and vegetable products. Contamination levels vary widely ($<10^1$ g^{-1} to 10^7 g^{-1}) and are summarized in Table 39–8.

Bacillus cereus is a particular problem to the dairy industry. It contaminates the udders of cows while they graze in the fields, contaminating the milk during milking (see Chapter 22). Spores are more hydrophobic than spores of other *Bacillus* spp., which makes them adhere particularly well to many types of surfaces.[6,38,39] This makes them particularly difficult to remove during cleaning and a difficult target for disinfection. *B. cereus* spores also have appendages or pili that are, at least partly, involved in adhesion.[38,39] Not only can these properties allow the spore to survive sanitation but they can also allow them to adhere to the epithelial cells of the intestinal tract (see Section 39.5.2).

The use of spores of *B. thuringiensis* as an insecticide may cause some confusion as this organism is indistinguishable from *B. cereus* on most microbiological media. It is important that nonenterotoxin strains of *B. thuringiensis* are used for crop spraying as enterotoxin-producing strains have caused food poisoning.[19,41] Consignments of vegetables containing spores of enterotoxigenic *B. thuringiensis* have been returned from Scandinavia back to the producing country, where their use as an insecticide is allowed (Granum, unpublished).

39.7 GROWTH, SURVIVAL, AND DESTRUCTION IN FOODS

Most strains of *B. cereus* are mesophilic and are able to grow in low-acid foods at temperatures down to 15° C and up to 55° C (optimum 30° to 40° C).[15,28,32,40] Some are psychrotrophic and able to grow at temperatures down to 4° to 6° C (maximum 30° to 35° C).[66,69] Spores are variable in their resistance to heat. Most are moderately heat-resistant ($D_{121°C}$ of 0.03 minutes), but some are markedly heat-resistant ($D_{121°C}$ of 2.35 minutes).[40] Spores of sero-

type 1 tend to be more heat-resistant than other serotypes.[49] In oil, $D_{121°c}$ values of up to 30 minutes may be obtained for spores. The emetic toxin of *B. cereus* is markedly resistant to heat and has been reported to survive 126° C for 90 minutes;[65] in contrast the diarrheal toxin is heat-sensitive and inactivated by heating at 56° C for 5 minutes. The diarrheal toxin may be produced by psychrotrophic strains at temperatures down to 4° C.[69]

Growth may occur between pH 5.0 and 8.8 (optimum 6.0 to 7.0) and at a_ws down to 0.93 depending on the acidulant and humectant.[40] Predictive models have been published showing the interactive effects of temperature, pH, sodium chloride, and carbon dioxide on the growth of *B. cereus*.[60] Spores are moderately resistant to disinfection (eg, *D*-value of 0.4 minutes in the presence of 150 mg kg^{-1} available chlorine at pH 7.0).[40]

Other food poisoning *Bacillus* spp. have similar growth and resistance characteristics.

39.8 DETECTION AND ENUMERATION

39.8.1 Enumeration of the Organism

Most isolations of *B. cereus* from foodstuffs and environmental samples are made by direct plating onto selective and diagnostic media. There are many such media,[68] but those most widely used are Mossel's mannitol-egg yolk-polymyxin agar (MYEPA)[47] and Holbrook and Anderson's polymyxin-pyruvate-egg yolk-mannitol-bromothymol blue agar (PEMBA).[36] Both media rely on the hydrolysis of egg yolk lecithin and absence of acid production from mannitol as diagnostic features for *B. cereus* and the use of polymyxin B (100 IU ml^{-1}) as the selective agent. The replacement of the phenol red in MYEPA by bromothymol blue in PEMBA gave better differentiation of *B. cereus* than other *Bacillus* spp., this differentiation being further improved by reducing the peptone concentration to 0.1%; actidione (40 µg ml^{-1}) is used in media when moldy food is examined. False negative reactions (lecithinase-negative strains of *B. cereus*) may occur, and overgrowth by acid-producing microorganisms may make the identification of *B. cereus* colonies difficult. False positives may occur, so confirmation tests should always be carried out. These may be rapid biochemical tests using the range of tests shown in Table 39–9 or the staining of cells from a suspect colony with a lipid stain followed by microscopic examination of the cells for the presence of lipid globules.[36] Replacement of the bromothymol blue in PEMBA by bromocresol purple, and reducing the incubation time from 48 to 24 h, has been claimed to improve the isolation of *B. cereus* from some foods.[61]

39.8.2 Detection of the Food Poisoning Toxins

The emetic toxin only can be detected by observing symptoms when food extracts are fed to primates or by treating HEp-2 cells with extracts and examining for vacuolation of the cells.[37]

Two commercial kits are available for detecting the diarrheal toxin. One, the Oxoid *Bacillus cereus* RPLA enterotoxin detection kit (Oxoid Ltd, Basingstoke, England) and, the other, the Tecra bacillus diarrheal enterotoxin visual immunoassay kit (Bioenterprises Pty, Australia). The Oxoid kit detects the L_2-components of one of the two, three-component enterotoxins that have been characterized (Beechar and Wong[10] in Table 39–6), and the Tecra kit detects the 45-kDa component of the other three-component enterotoxin (Lund and Granum[44] in Table 39–6). Thus neither test specifically detects the biologically active toxin[11,44] although the results of the Tecra kit correlate with cytotoxicity.[16]

39.9 PREVENTION AND CONTROL OF *BACILLUS* FOOD POISONING

Bacillus cereus food poisoning is principally associated with the storage of cooked foods at tempera-

Table 39–9 Identification of Common Food Poisoning Strains of *Bacillus* species[53]

tures and for times that allow growth to occur and the number of vegetative cells produced to exceed 10^6 ml^{-1} or g^{-1}. Thus rapid cooling of cooked foods to <10° C is generally an effective control measure. Low pH foods (< pH 5.0) and dry foods will not support the growth of *B. cereus,* although many dried foods will be contaminated with spores of this microorganism.

There are many reports of food poisoning occurring when dried foods are rehydrated and stored at temperatures at which growth can occur. The emetic syndrome form of *B. cereus* food poisoning, often associated with consumption of rice in Chinese restaurants, is an example of food poisoning arising from such a practice. A common cause results from saving portions of boiled rice from one day to the next and then using it to produce fried rice. The rice often is stored at room temperature as this results in the best form of rice for frying, but also provides ideal conditions for the growth of *B. cereus.* Educating Chinese restaurant owners to cool boiled rice in thin layers after bulk cooking and then refrigerating any rice stored from one day to the next has significantly reduced the incidence of food poisoning associated with the consumption of rice in Chinese restaurants in the UK.

The frequent contamination of milk with spores of psychrotrophic strains of *B. cereus* is of concern to the dairy industry as the growth of such spores causes spoilage (aggregation of the fat in the cream layer of pasteurized milk, often called "Bitty Cream") and "Sweet Curdling" (without pH reduction) of homogenized and nonhomogenized milk). *B. cereus* contamination of pasteurized milk is also potentially a food poisoning concern. However, evidence from trials of human volunteers consuming milk naturally contaminated with *B. cereus* and stored at refrigerated temperature indicates that the risk of *B. cereus* food poisoning from chill-stored refrigerated milk is low.[43] However, it is important to keep the level of *B. cereus* in milk as low as possible by cleaning the udder and teats of the cows prior to milking; cleaning, and disinfecting milking equipment, pipework, and storage vessels and by the storage of the milk at temperatures and for times that prevent *B. cereus* concentrations exceeding 10^4 ml^{-1} (see Chapter 22). Similar considerations to the control of *B. cereus* in milk apply to the control of *B. cereus* growth in preprepared, extended shelf life, chill-stored meals.

Food poisoning caused by the *Bacillus subtilis* group of organisms also is associated with poorly stored cooked foods. Vehicles include meat pies, rice dishes, and other cereal-based products such as bread and pizzas (Table 39–7). Control measures are the same as those applied to *B. cereus.*

39.10 CONCLUDING REMARKS

Bacillus cereus food poisoning is widespread, with the diarrheal type found mainly in the Western hemisphere and the emetic type in the Eastern hemisphere; this difference reflects the different types of foods consumed in these countries. The symptoms of poisoning are typical of many gastrointestinal infections and intoxications, these being relatively mild and of short duration. Principal foods of concern are dairy and cereal-based products. The psychrotrophic strains capable of growth at refrigerated food temperatures are of concern in all low-acid, extended shelf life, chill-stored foods. Further research is needed into the ability of these organisms to grow in these foods and to produce food poisoning toxins. The types, structure, and composition of the enterotoxins of *B. cereus* need much further study. There is a need for an *in vitro* test for the emetic toxin (cereulide) and a specific test for biologically active diarrheal toxin(s).

40.1 INTRODUCTION

The disease-causing, enteropathogenic *Campylobacter* spp., transmitted primarily through foods to humans, consist mainly of the species *C. jejuni*, but may also include *C. coli, C. lari*, and *C. upsaliensis*.[83] We shall refer to these four species as campylobacters in this chapter. These fascinating, and all too frequently occurring human pathogens, have previously been labeled as "newly emerging" or "newly recognized." In 1957, E.O. King was first to suggest that human infections were caused by what she called "related vibrios." Twenty-five years after being emergent and becoming substantially recognized[28] as the most frequently isolated bacterial agent implicated in human gastroenteritis, such a label no longer fits.

Campylobacters are easily destroyed by drying,[51] relatively modest cooking, or processing procedures.[83] The organisms are fragile and pose a health problem only if foods are prepared using poor hygiene or are consumed before being thoroughly cooked. Consequently, the food handler should be able to prevent transmission through food products.[38]

The primary ecologic niche for campylobacters is the intestinal tract of warm-blooded animals. Their minimum growth temperature is about 30° C;[93] therefore, there are few situations in which they are likely to multiply in foods. Measures to reduce contamination with campylobacters during animal production, and during the processing of raw products, should be used as the main means of reducing the incidence of illness caused by these organisms.

40.2 TAXONOMY AND CHARACTERISTICS OF THE ORGANISMS

Campylobacter characteristically is Gram-negative, has narrow (0.2 to 0.5 µm) and long (1.5 to 5.0 µm) rods, is spiral-shaped and nonspore-forming, and contains a single polar flagellum on one or both ends that produces the characteristic corkscrew-like motility. *Campylobacter jejuni, C. coli*, and *C. lari* cause more than 90% of the reported human disease. These species grow well at temperatures ranging from 37° C to 42° C, but should not be considered as thermophilic because they die at temperatures at or above 45° C. Older cultures often become coccoidal. It is unclear whether this morphological change confers an advantage toward survival or whether this is cellular deterioration leading eventually to death. Viable, nonculturable forms may arise under conditions of starvation.[149] The genus is oxidase-positive and reduces nitrate to nitrite. The organism does not ferment or oxidize carbohydrates; it derives its energy through accessing a variety of tricarboxylic acid (TCA) intermediates or by decarboxylation and deamination of amino acids. Although oxygen is characteristically the terminal electron acceptor in the TCA cycle, the organism does not tolerate levels of oxygen normally found in the atmosphere, but grows optimally in microaerobic conditions. Most enteropathogenic campylobacters are catalase-positive. The organisms are thus ideally suited to their primary niches in the reproductive and intestinal tracts of warm-blooded animals.[126]

40.3 CHARACTERISTICS OF THE DISEASE

Symptoms of infection in humans are usually severe: watery and/or bloody diarrhea; abdominal pain that can be of such severity as to mimic appendicitis; and malaise, fever, and headaches also occur. The incubation period following ingestion is 2 to 5 days. Diarrhea caused by campylobacteriosis can vary from merely loose to profuse stools, which may contain blood, be slimy, and may be extremely foul smelling. Individuals often experience more than eight bowel movements in a day. Symptoms usually subside in less than 7 days, and are most severe 2 to 5 days after onset. Active excretion of the organism and disease symptoms can recur.[20,29] An infectious dose for humans may be as few as 500 cells.[11,146] However, considerable variation exists because of differences in virulence of campylobacter strains and in host resistance. Campylobacteriosis is typically a self-limiting disease. Antibiotic therapy should be considered only if complications and recurring episodes occur; erythromycin is frequently a highly effective treatment.[20] Hospitalization due to campylobacteriosis is reported less often than for salmonellosis or listeriosis but may account for 10% of cases; deaths are rare.[36]

40.4 MECHANISM OF PATHOGENICITY

The mechanism of pathogenicity is unclear. Because clinical symptoms of *Campylobacter* infections resemble those manifested by other enteropathogens, it is reasonable to presume that similar mechanisms may be involved. *Campylobacter* infection of humans results in high titers of humoral IgG, IgM, and IgA.[92] This could indicate that bacterial cellular constituents pass from the intestinal tract across the epithelium. Once on the serosal side, these antigens are presented to the immune system receptors and the cellular and humoral constituents are able to respond. Poor antibody response to *Campylobacter* infection is associated with patients who have prolonged or intermittent enteritis.[153]

Campylobacter diarrhea in developed countries is characterized by polymorphonuclear leukocytes in 78 to 93% of cases and blood in diarrhea specimens from 60% to 65% of the cases.[14] This is very different from the watery, noninflammatory diarrhea frequently observed in tropical regions.[32,64,176] The mechanisms of pathogenesis of *Campylobacter* may include association with and attachment to the intestinal epithelium, invasion of the epithelium, and/or toxin formation. Guerrant et al.[69] studied 12 isolates of *C. jejuni* from individuals with inflammatory diarrhea, all of which produced factors lethal to HeLa cells; four were cytotoxic also to CHO cells.[98] Cytotoxicity was not neutralized by the Shiga toxin antiserum. The mechanism and the receptor involved in this cytotoxicity are not yet known.

Enteropathogenic *Campylobacter* adhere to epithelial cells.[83,155] Adherence is related to an outer membrane protein (OMP) with a molecular weight of 27 kDa that binds to the host membrane. The outer membrane protein may be a major virulence factor. Other potential virulence factors have also been reported.[111] Ruiz-Palacios et al.[153] reported a strong association between enterotoxin production by *Campylobacter* isolates and illness; however, they did not find an association between cytotoxin production and diarrhea. They suggested that the mechanisms of interaction and the membrane receptors may be different for adherent and invasive strains. There is evidence that isolates from developing and developed countries show similar enterotoxicity, and it was suggested that the difference in clinical symptoms could be explained by the immune status of the exposed individuals affected.[138]

Campylobacters reside in the deep crypts lining the intestinal tract. The organism is highly motile and its spiral shape allows movement into the crypts of Lieberkuhn through the mucin layer adjacent to the gut surface.[9,104] Hugdahl et al.[78] demonstrated components of gastric mucin (especially L-fucose and L-serine) to be chemotactic attractants; Nachamkin et al.[120] reported that campylobacter flagella served a critical role in the colonization of chicks. Mutants without flagella were unable to colonize chicks, while the wild type readily did so. Although pathology is not manifested in chickens, the first phases in mucosal colonization may be similar in poultry and in humans. Consistent, inexpensive, and readily available animal virulence models are lacking and, as indicated above, various tissue culture assays showing enterotoxin or cytotoxin activities of the organism have been inconsistent and have yielded controversy.

Increasingly reported are the far more serious sequellae to the initial acute phase of enteritis. *Campylobacter* infections can cause reactive arthropathies, Reiter's syndrome, Guillain-Barré syndrome (GBS), and associated neurological disorders. People infected with the human immunodeficiency virus are particularly susceptible to *Campylobacter* enteritis[163] just as they are to other infections. In Los Angeles County, the incidence of *Campylobacter* enteritis in acquired immune deficiency syndrome patients was 519 patients per 100,000, whereas in general population it was 13 per 100,000 individuals.

Infection with *C. jejuni* can also lead to reactive arthritis.[35,154,185,187] This involves the inflammation of joints at a location distant from the enteric site of infection. The inflammation is sterile and develops within days to weeks after the acute phase of infection. Antibody levels against *C. jejuni* are elevated but the organism cannot be isolated from the infected joint.

The costs of *Campylobacter* enteritis each year within the United States (US) are estimated from $156 million[181] to $4 billion.[60] In 1995 the annual costs of campylobacteriosis in the US were estimated to range from $362 to $699 million.[27] More recently, Buzby and colleagues estimated costs for cases of US campylobacteriosis as ranging from $1.17 billion to $1.37 billion annually.[31] A study in 1997 estimated that reported incidents incurred costs of at least 4.5 million dollars and that actual figures may be 10 times this amount for New Zealand. These estimates do not include the enormous expenses associated with the sequellae attributed to *Campylobacter* infection. Nor do they include the pain and suffering endured by both the infected individual and their families who are afflicted with these complications of the enteric infection, such as motor axonal neuropathy, Reiter's syndrome, and GBS.[58,114]

40.5 INCIDENCE OF THE ORGANISMS IN THE ENVIRONMENT AND IN FOODS

40.5.1 General Incidence in the Environment

Animals used for food production and domestic pets often are reservoirs for campylobacters.[21] These bacteria generally are commensal organisms in the intestinal tract of a wide variety of animals; however, they occasionally serve as enteric pathogens in the young of some species such as calves, lambs, and puppies.[159] *Campylobacter jejuni* is found commonly in the intestinal tract of birds, cattle, and sheep, whereas *C. coli* is most often associated with pigs.[46] In developed countries, asymptomatic excretion of campylobacters by human carriers is uncommon; therefore, humans serve as only a minor reservoir. However, humans may transfer campylobacters into animal production and food-processing areas on contaminated clothing (boots or gloves) or through inadequate personal hygiene. In developing countries, where proper hygiene is often more difficult to practice, human carriage may be more important in disease transmission.[21] A study in Washington state showed that campylobacters may be isolated from environmental sources such as ponds, lakes, and creeks.[33] No correlation was found between incidence of campylobacters and fecal bacteria. Generally, higher rates of isolation were noted in fall and winter when the water temperature is lower, extending the time the organism can survive outside the intestinal tract of its animal host.[33] Unhygienic water sources have been associated with numerous outbreaks of campylobacteriosis where adequate levels of chlorination and the operational integrity of community water systems were not maintained properly.[112,148,155,180] Campylobacters have been isolated from sea water, streams, rivers, and estuaries that have been tainted by fecal contamination from wild or domestic animals.[98] Campylobacters survive better in cool, fresh water[17] than in warm or brackish water.[98] Harris[73] determined that raw milk and mushrooms were the only nonmeat foods consumed that were linked to campylobacteriosis. Doyle and Schoeni[52] isolated *C. jejuni* from only 3 of 200 (1.5%) packages of retail mushrooms. Park and Sanders[131] sampled outdoor market produce and detected campylobacters in spinach, lettuce, radish, green onions, parsley, and potatoes at 1.6% to 3.3% incidence. No campylobacters could be detected following minimal sanitization.

40.5.2 Incidence in Poultry and Poultry Products

Chickens, turkeys, domestic ducks, pheasants, guinea fowl, emu, and ostrich have all been associated with high rates of colonization by *C. jejuni*.[74,108,118,126,166] Campylobacters have been isolated also from hawks, parrots, and pigeons.[34,126] By far the most important avian species associated with human exposure to *C. jejuni* is the chicken.[42] Most of the 7 billion birds produced within the US in 1996 were raised under intensive management conditions,[183] though free-range birds have also been shown to be colonized by *C. jejuni* at a similar rate.[183] Cloacal swabs were taken from poultry raised under intensive and free-range management respectively. Rates of isolation appear similar among intensive-reared and free-ranged bird flocks.[5] *Campylobacter jejuni* usually is not isolated from the hatchery, nor is it typically isolated from the production environment during the first two weeks after chicks are placed; however, by the third or fourth week of production, most flocks are contaminated to some extent and the organism eventually spreads to almost all members of the flock. The intestinal tract of chickens may harbor up to 10^7 cfu *C. jejuni* g^{-1} without any apparent pathological consequences for the host.[168] During processing, poultry carcasses may become contaminated by the release of intestinal contents;[121] most raw poultry products are contaminated with *C. jejuni*.[21,166]

40.5.3 Incidence in Pigs and Pig Products

Campylobacters are often found in the intestinal tract of swine and are sometimes associated with enteric disease in pigs;[21,121] most isolates are *Campylobacter coli* rather than *C. jejuni*. Swine carcasses are more frequently contaminated with campylobacters than either cattle or sheep carcasses.[60] However, the reported rate of contamination from swine carcasses varies widely from 2.9% in Poland[101] to 16.9% in Canada[102] and 95% in Sweden.[177]

40.5.4 Incidence in Cattle, Beef, and Cow's Milk

Cattle have been implicated in numerous outbreaks of human campylobacteriosis, primarily associated with the consumption of unpasteurized milk.[14,141,147] Milk may become contaminated by exposure to fecal material[186] or through mastitic infection.[116,125] Cattle as a meat source is not strongly implicated in transmission of campylobacters to humans. Although healthy cattle may excrete *C. jejuni* in their feces and carcasses may become contaminated during processing, this occurs infrequently and the numbers of contaminants are low.[121] Stern et al.[170] analyzed samples of beef liver, beef cheek meat, and ground beef using presence/absence testing (minimum level of detection was 10 cells) and found that only about 5% of red meat samples from retail outlets around the US were positive for campylobacter. An earlier study,[182] which employed both enrichment and direct-plating techniques, found only 1.6% of 6,169 meat samples positive for the organism.

40.5.5 Incidence in Sheep and Sheep Products

Campylobacter jejuni lives as a benign commensal organism in the intestinal tract of some sheep[21] but may cause infectious abortion in others.[161] Isolation of the organism from the intestinal contents of sheep is common and contamination of carcasses can occur.

40.5.6 Incidence in Domestic Pets and Other Animals

Domestic pets such as dogs and cats may harbor campylobacters in their intestinal tracts and may serve as important reservoirs for human infection. Moreno et al.[115] isolated campylobacters from 66% of healthy cats and 34% of healthy dogs. Campylobacter isolation rates are higher among young puppies and kittens than in mature dogs and cats,[20] and the pathogens are isolated more frequently from kennel populations than from household pets.[26] More exotic pets such as the golden Syrian hamster may harbor campylobacters as may numerous zoo animal species including ungulates, felines, and primates.[108] Wild rodents[57] and flies[151] may also carry campylobacters and could be important vectors in contamination of poultry houses. Campylobacters are isolated infrequently from reptiles probably because of the high (42° C) optimum growth temperature for the microorganism.[108]

40.6 EPIDEMIOLOGY

The epidemiology of human campylobacter infection reflects a pattern of numerous sporadic, individual infections and relatively infrequent large outbreaks. In sporadic cases of campylobacteriosis occurring among members of a health maintenance organization in Seattle, about 50% were accounted for by poultry[73] and could be traced to the mishandling of contaminated poultry products. Among university students in Georgia, 70% of cases were accounted for by eating chicken, often undercooked or raw.[178] In another study in Colorado, handling raw chicken, as opposed to eating it, emerged as a risk factor.[77] Poor kitchen hygiene may also play a role, and in one study the risk of infection was inversely associated with the frequency of using soap to clean the kitchen cutting board.[178] Further studies in many countries have shown that *C. jejuni* serogroups isolated from poultry sources are the same as some of the predominant serogroups isolated from humans.[7,8,61,90,91,117,123,142,150,152] *Campylobacter* isolates from swine (typically *C. coli*) do not belong to serotypes found in humans; therefore, pigs do not appear to be a major vector for human campylobacteriosis. Although as noted above, cattle are an important source of milkborne campylobacteriosis, meat products are not strongly implicated.[166]

Skirrow[158] and Blaser[13] reported isolation rates of *C. jejuni* of 7.1% and 5.1%, respectively, from the stools of patients with gastroenteritis. Prior to these early reports, clinical laboratories responsible for isolation and identification of causative agents of foodborne illness did not culture stools at 42° C under reduced atmospheric conditions (microaerobic atmospheres) and therefore failed to detect campylobacters.

In many countries, including the Netherlands, the United Kingdom (UK), France, Italy, Sweden, the US, and Australia, campylobacters are the main cause of acute infectious diarrhea. The estimated annual incidence for campylobacteriosis in the US in 1988 was approximately 1,000 cases per 100,000 population[179] and is close to the annual estimated infection rate in England and Wales of 1.1%.[96] In the US in 1996, FoodNet began collecting population-based active surveillance data on culture-confirmed cases of seven foodborne diseases, including campylobacteriosis. Incidence rates in stool specimens or specimens from normally sterile sites were highest for campylobacteriosis at 25 per 100,000 population; rates ranged from 14 (Georgia) to 58 (California).[36] In 1996, the British Public Health Laboratory Service Communicable Disease Surveillance Centre received a total of just over 43,000 laboratory reports of campylobacteriosis; numbers of reports received in the first 20 weeks of 1997 were 7% higher than in the same period of 1996.[109] A study conducted in the Netherlands in 1992 and 1993 yielded an annual incidence of campylobacter infection of 69 cases per 100,000 people.[65] However, the true incidence of campylobacteriosis in the general population is likely to be much higher, because only a small proportion of people with gastrointestinal complaints consult a physician, as discussed in Chapter 37. In developed countries, the demographic incidence of campylobacteriosis usually follows a bimodal distribution with infection occurring most frequently in children under the age of 4 years and in young adults between 20 and 30 years of age.[179] In developing countries *Campylobacter* infection occurs most frequently in children under 5 years of age with a prevalence of infection much greater than in developed countries.[21] For children aged less than 1 year, rates per 100,000 population for campylobacteriosis ranged from 25 (Georgia) to 193 (California) in the US in 1996.[36]

When outbreaks of campylobacteriosis occur, they are most often associated with consumption of raw, unpasteurized milk or milk that has been contaminated postpasteurization.[88] Outbreaks generally demonstrate a bimodal distribution with peaks in May and October.[121] By contrast, the far more numerous sporadic cases of campylobacteriosis are associated with consumption of foods of animal origin, and the seasonal incidence of infections typically demonstrates a summertime peak[30] suggesting different epidemiological characteristics for outbreak-associated and sporadic cases. The Centers for Disease Control and Prevention (CDC) Foodborne Diseases Active Surveillance Network reported that 35% of the sporadic cases occurred during the summer months (June-August).[36]

The importance of food handlers in transmission of *Campylobacter* infection has not been fully defined, nor has the role of person-to-person contact. Two cooks who were asymptomatic excreters of *C. jejuni* did not transmit the pathogen to prepared foods.[122] However, campylobacters were isolated from the hands of a food handler suffering from campylobacteriosis.[15] Person-to-person transmission of *Campylobacter* can occur and studies in Canada[128] and England[88] demonstrated that transmission from ill children to family members occurred frequently. By contrast, in two outbreaks among Japanese children secondary transmission was not observed.[84,191]

Perinatal transmission of *Campylobacter* infection is possible, although rare. Pregnant women infected with *Campylobacter*-associated bacteremia may pass on a severe systemic infection to the fetus.[21] A case of maternal sepsis caused by *C. jejuni* was reported in Switzerland, in which the etiologic agent was confirmed using molecular methods on placental tissues.[113] It is also possible for neonates to acquire infection during or shortly after birth. Anders et al.[6] reported seven cases of *Campylobacter* enteritis in neonates over a 2-year period in Denver in which symptoms began from 2 to 11 days after birth.

Direct animal contact also is responsible for transmission of *Campylobacter* infections to some humans. Among people living in farming communities, a higher incidence of campylobacteriosis is observed in those who have occupational exposure to poultry and cattle.[87] Likewise, serological surveys demonstrated that people employed in poultry and red meat plants have a significantly higher rate of seropositivity to *Campylobacter* antigens than rural field laborers.[87] Contact with household pets such as cats and dogs may also be responsible for transmission of *Campylobacter* infection, as similar bio- or serotypes are frequently isolated from humans and animals.[19] Newly acquired puppies and kittens are generally a greater risk factor than are older adult animals, especially if the pet develops diarrhea.[122] Studies conducted in England reported 3 cases of *Campylobacter* infection associated with cats and 97 cases associated with dogs.[160]

40.7 FACTORS AFFECTING SURVIVAL, GROWTH, AND CONTAMINATION OF FOODS

Campylobacters do not grow below 30° C or in the presence of atmospheric levels of oxygen. Therefore, growth of campylobacters in food is not a consideration, though survival of the organism on contaminated foods is a concern in view of the low infective dose.[47] Factors that affect the survival of campylobacters include: temperature (heating, refrigeration, and/or freezing), pH, sensitivity to sodium chloride (NaCl) or spices, atmospheric conditions, irradiation, and food preparation.[83] Viable, nonculturable campylobacters have been reported.[149] Contamination of poultry meat is thought to originate from the intestinal tract and then spread to the meat during transport and processing.[118] Generally, counts are at their highest immediately following evisceration, though for contaminated broiler carcasses $10^{2\text{-}3}$ cfu campylobacter ml^{-1} of carcass rinse are common when sampled from the chiller. Prior to further processing or transport to a retail market, carcasses and other poultry products may be stored under chilled or frozen conditions; although the organism survives frozen storage, survival is generally better under chilled storage. Hanninen[70] studied survival of four strains of *C. jejuni/coli* on frozen broiler carcasses. During 12 weeks of storage at –20° C counts decreased from an initial inoculum of between 10^3 and 10^5 g^{-1} to between $10^{0.5}$ and 10^2 g^{-1}. Oosterom et al.[124] reported that freezing affected *C. jejuni* viability only during the first few hours, and after an initial drop in numbers, it survived well on chicken carcasses and chicken livers stored at –20° C for more than 64 and 84 days, respectively. Stern et al.[170] collected approximately 800 fresh and frozen meat and poultry meat samples and analyzed them for *C. jejuni*. Overall fresh versus frozen isolation rates were 12.1% and 2.3%; for poultry samples, these were 21.3% and 7.5%, respectively. In another study, in the same year, Stern et al.[170] compared isolation rates from naturally contaminated carcasses (two groups of 15 broilers) before and after applying a freeze-thaw cycle. By direct plating, the percentage of positive carcasses decreased from 95% to 20% due to freeze-thaw injury (–15° C for 14 days); by enrichment, detection decreased from 90% to 53%.[172] Selective enrichment is essential for isolation of the organism from the frozen carcasses as cells of *C. jejuni* are injured by freezing.[144] Beuchat[10] demonstrated the survival of four of five strains of *C. jejuni* at –18° C for 12 months. He found that direct plating was superior to a most probable number (MPN) technique but that enrichment in Doyle and Roman's enrichment broth resulted in the highest level of detection. Stern[167] stored uninoculated carcasses (initial level of contamination, 6.3 x 10^5) at 4° C and sampled them at 0, 1, 3, 7, and 10 days. Using an enrichment method, detection rates of 86%, 88.75%, 81.25%, 80%, and 31.43% were reported, respectively; by direct plating, the organism was not detected after 10 days' storage.

Campylobacter jejuni grows at temperatures between 30° C and 45° C, with optimum growth at 42° C to 43° C;[173] death is more rapid at 25° C than at either 4° C or 30° C.[12,48] Heat injury of *C. jejuni* occurs at 46° C and thermal inactivation occurs at 48° C. Doyle and Roman[51] determined rates of thermal inactivation for five strains of *C. jejuni* in skim milk. At 48° C, *D*-values ranged from 7.2 to 12.8 minutes while at 55° C they ranged from 0.74 to 1.00 minutes. *D*-values for *C. jejuni* were greater in ground chicken meat than in peptone medium.[12] Thus at 49° C, 51° C, 53° C, 55° C, and 57° C, *D*-values in peptone were 15.2, 4.90, 1.71, 0.64, and 0.25 minutes, respectively, while in ground chicken, *D*-values were 20.5, 8.77, 4.85, 2.12, and 0.72 minutes, respectively. *D*-values for inactivation of campylobacters in ground beef ranged from 5.9 to 6.3 minutes at 40° C and from 2 to 21 seconds at 58° C, and in lamb meat *D*-values at 50° C ranged from 5.9 to 13.3 minutes and at 60° C from 12.5 to 15.8 seconds.[99] These data indicate that ordinary cooking temperatures should be sufficient to destroy campylobacters contaminating poultry and other meats.

Optimal growth of *C. jejuni* occurs at pH 6.5 to 7.5, with good growth at pH 5.5 to 8.0, and no growth below pH 4.9.[48] At pH 3.0 to 4.5 the rate of cell death decreased with decrease in temperature. Campylobacters are highly sensitive to NaCl (optimum growth concentration is 0.5%); sensitivity to NaCl is also temperature dependent.[50] Thus, at 4° C, *C. jejuni* was sensitive to 1.0% or more NaCl but the rate of death at this temperature was much less than that which occurred at 25° C; a 3 $\log_{10}$ decrease of cells occurred in the presence of 4.5% NaCl, after 1.25 to 2.1 days at 25° C, but a similar reduction at 4° C took about 2 weeks at the same salt concentration. Two strains of *C. jejuni* and *C. coli* tolerated more NaCl at 35° C than at 30° C.[71] Abram and Potter[2] investigated survival of *C. jejuni* in ground chicken, beef, and cod with 0%, 1%, and 2% added NaCl at –18° C, 6° C, and 10° C over a 5-day period. The survival of *C. jejuni* during frozen storage was not affected by NaCl levels tested, but at 6° C and 10° C, in both raw and cooked chicken and beef, significant decreases in cell numbers occurred with increasing NaCl concentration. Substantial decreases in cell numbers also occurred in refrigerated raw cod but there was less decrease in the cooked fish; numbers in raw cod decreased significantly with increasing NaCl concentration and the decline was more pronounced during storage at 10° C than at 6° C. These data suggest that even moderate levels of NaCl in foods can decrease *C. jejuni* survival. Deibel and Banwart[41] studied the effects of various concentrations of oregano, sage, and ground cloves on the growth of *C. jejuni* in a liquid growth medium incubated at 4° C, 25° C, and 42° C for up to 48 hours. At 42° C, growth occurred at the highest concentrations of spice tested, after 16 hours. At 25° C, greater than a 3 $\log_{10}$ decrease in colony forming units was observed in the suspensions containing sage or oregano, with sage showing the greatest effect. At 4° C, a less than 1 $\log_{10}$ reduction was observed for all concentrations of spice tested. Koidis et al.[100] determined the inhibitory effect of garlic, onion, black pepper, and oregano on survival of *C. jejuni* in a nutrient broth stored at 4° C for 12 days. At the highest concentration tested, a 3.9 $\log_{10}$ decrease was noted for the broth containing onion, while 3.0 $\log_{10}$ reductions below the respective controls (nutrient broth alone) were noted for broths containing the maximum concentrations of garlic, pepper, and oregano tested. Clearly, survivability is affected by the presence of spices. However, given the length of time required for substantial reductions in numbers to occur and the levels of spices tested, the practical application of the effect is questionable. Some effect may occur on the surface of a spiced meat product, where exposure to drying and oxygen occur, but these conditions alone are lethal to campylobacters.[51]

Outbreaks of campylobacteriosis from the consumption of contaminated milk have been documented;[16,54] therefore, survival of campylobacters in milk and milk products is of public health concern. The ability of campylobacters to survive heat treatment in milk has been evaluated.[63] The legal minimum requirement for pasteurization of milk in most countries is heating at a temperature of at least 72° C for not less than 16 seconds (see Chapter 22). Properly controlled pasteurization at 72° C inactivated campylobacters inoculated into milk, reducing counts from up to 10^6 ml^{-1} before pasteurization to undetectable levels after pasteurization.[63] In the case of one human isolate inoculated into milk at an initial concentration of 10^6 ml^{-1}, survivors were detected after heating at 72° C for 10 seconds but not after heating for 20 seconds. Variable rates of die-off in milk have been reported[48] with one strain showing only a 2 $\log_{10}$ decrease in viable cells after 14 days of refrigerated storage and another showing a greater than 10^6 log decrease after only 7 days at the same temperature; inactivation corresponded to increases in milk aerobic plate count and a decrease in milk pH. Ehlers et al.[53] inoculated milk to be used in the manufacture of cheddar cheese with 10^2 to 10^6 cells ml^{-1} of *C. jejuni* and found no viable cells in the curd after 30 to 60 days of curing.

A number of countries permit the use of gamma irradiation as a means of preserving foods, and the use of 3.0 kGy applied to poultry, specifically to control levels of salmonellae, was approved in the US in 1990.[56] Clavero et al.[37] inoculated raw ground beef patties with *C. jejuni* and subjected them to gamma irradiation treatment (^{60}Co) at varying doses. Effects of fat, freezing, and refrigerated temperatures were investigated. Regardless of fat level or temperature during inactivation, a 2.5 kGy dose inactivated $10^{10.6}$ *C. jejuni* g^{-1} of beef. Patterson[132] investigated the sensitivity of *Campylobacter jejuni*, *C. coli*, and *C. lari* to irradiation in poultry meat; D_{10} values obtained ranged from 0.12 to 0.25 kGy. There was no significant difference in the radiation sensitivity between species and between strains of the same species. Collins et al.[39] compared the ability of *C. jejuni* and *Arcobacter butzleri* to survive irradiation under vacuum in ground pork; D_{10} values for *A. butzleri* and *C. jejuni* were 0.27 kGy and 0.19 kGy, respectively. Based on these values, they predicted a 5 log decrease in *A. butzleri* cells and a 7 $\log_{10}$ reduction in *C. jejuni* cells following a 1.5 kGy treatment. Enteropathogenic *Campylobacter* is more sensitive to irradiation than either *Listeria monocytogenes* or *Salmonella*, and treatments sufficient to eliminate these pathogens from poultry carcasses would also eliminate campylobacters.

The survival of *Campylobacter* in foods is affected by the atmosphere. Blankenship and Craven[12] reported an increase in survival in chicken drumsticks when stored in carbon dioxide (CO_2) compared with an ambient atmosphere. After storage for 24 days, a 2 $\log_{10}$ decline in cell numbers was noted in the air-stored compared with the CO_2-stored meat. However, Wesley and Stadelman[188] evaluated the effect of CO_2 environment on 50 broiler carcasses over a 9-day period and reported no effect due to the modified atmosphere. The discrepancy between these two reports may be due to differences in the time for which samples were stored (9 vs. 24 days). In fresh beef samples inoculated with *C. jejuni* and then stored in three atmospheres (100% N_2; 20% CO_2 + 80% N_2; 5% O_2 + 10% CO_2 + 85% N_2) at 20° C or 4° C for 2, 4, and 25 days, survival at 4° C was similar for all three of the modified atmospheres, but the highest survival was in 100% N_2. Stern et al.[171] reported no significant difference in survival of *C. jejuni* in broiler chickens, when vacuum-packed or wrapped in oxygen-permeable, polyvinyl chloride film. However, vacuum-packed red carcass meat samples, stored refrigerated for 1 week, gave a significantly ($P<0.01$) higher rate of recovery of indigenous campylobacters than oxygen-permeable film-wrapped samples (19/63 vs. 7/63). The survival of *C. jejuni*, inoculated onto turkey roll and packed under CO_2, increased as the concentration of CO_2 was increased, at both 4° C and 21° C storage temperatures.[139] Grigoriadis et al.[68] investigated storage of hamburgers in 100% air, 100% CO_2, and 100% N_2 atmospheres at 4° C. An atmosphere of 100% air was the most toxic to the *C. jejuni* strains tested.

As early as 1983, Hopkins and Scott[77] found a correlation between handling raw chicken and incidence of sporadic campylobacteriosis. In a 2-year study to evaluate the prevalence of indicator bacteria and specific pathogens in 10 normal kitchens in the US, *Campylobacter* was isolated from the sinks of two houses, indicating that the organism can survive in the environment of a kitchen.[89] Acuff et al.[4] investigated washing procedures used for contaminated utensils (knives and cutting boards) and by food handlers for washing their hands, for their effectiveness at destroying *C. jejuni* after use in the handling and preparation of inoculated turkey thighs. Washing of utensils with water and detergent, either by hand or in a dishwasher, removed *C. jejuni* except from wooden cutting boards washed by hand. However, hand washing procedures, unless thoroughly applied, may not ensure complete removal of the organism from contaminated hands. *C. jejuni* cells survived better on wooden than plastic surfaces because of the physical structure of the wood.[25]

40.8 PRINCIPLES OF DETECTION, ISOLATION, IDENTIFICATION, AND TYPING

40.8.1 Detection, Isolation, and Identification

With the possible exception of raw poultry, which may harbor sufficiently large numbers of *C. jejuni* to enable their detection and enumeration by direct plating, most products require the use of enrichment methods to detect the small numbers of campylobacters that may be present. Some of these may be injured requiring particular conditions for their recovery.[129] Proper sample care, a large sample size, and the use of a selective enrichment broth, proper incubation conditions (including the correct atmosphere and temperature), and the plating of enrichments on to suitable selective plating media are essential for the reliable isolation of campylobacters from foods.[173]

Because of the fragility of campylobacters, food samples must be held under suitable conditions and processed rapidly to ensure optimum isolation. Thus food samples for analysis should be protected from exposure to air, transported under refrigeration or packed in ice (but must not be frozen), and analyzed as soon as possible after the collection of the sample.

The characteristics of campylobacters that make culture most difficult are their microaerophilic and capnophilic (CO_2-loving) nature. Oxygen at atmospheric concentration (21%) is toxic to campylobacters, which prefer only 5% oxygen and about 10% CO_2. Microaerobic conditions for growth of campylobacters can be achieved by a variety of methods including application of the Fortner principle[95] or atmosphere generating systems and gas exchange using pressurized gas cylinders to flush and fill anaerobe jars or sealable plastic bags.

Many different enrichment broths[24,49,130] and selective plating media[14,23,175] have been developed for recovery of campylobacters from foods. Most of these media use a basal medium consisting of beef extract, peptone, yeast extract, and NaCl to which supplements are added such as lysed or laked horse or sheep blood; charcoal is used in place of blood in some plating media. The aerotolerance of campylobacters in food samples can be optimized for improved recovery of the organism by supplementing the growth media with 0.025% each of ferrous sulfate, sodium metabisulfite, and sodium pyruvate (FBP supplement).[62] The selectivity of the enrichment media is increased by the addition of various antibiotics including amphotericin B, cefoperazone, cycloheximide, polymixin B, rifampicin, trimethoprim lactate, and vancomycin.

Sampling procedures are similar to those used for microbiological analysis of foods for other pathogens and usually involve either rinsing or surface swabbing techniques. The surface rinse technique is especially useful for poultry carcasses or other moderately large pieces of food. The food sample is aseptically placed in a sterile plastic bag and 100 to 250 ml of brucella broth, buffered peptone water, or other suitable diluent is added. The sample is rinsed by shaking and massaging. The rinse suspension may then be filtered, if necessary, through layers of cheesecloth to remove particulate matter. The suspension may then be swabbed directly onto *Campylobacter* selective agar or serial dilutions may be plated if enumeration is desired. Alternatively, a portion of the rinse suspension may be mixed with an equal volume of double strength selective enrichment broth. This inoculated enrichment broth can be incubated directly and used for qualitative determination of *Campylobacter* presence or it can be further diluted and used to inoculate further tubes of media for quantitative estimation by the MPN technique (Chapter 60). If very small numbers of *Campylobacter* are expected, the original rinse suspension may be pelleted by centrifugation at 16,000 × g for 10 min. The supernatant may be discarded and the pellet resuspended in a lesser volume of about 2 to 5 ml of enrichment broth. Incubation usually is carried out under microaerobic conditions (eg, 5% O_2, 10% CO_2, 85% N_2) at 42° C for 24 to 48 hours with agitation. Recovery of injured campylobacters is facilitated by initial incubation at 37° C for 4 hours, at which time antibiotic supplements are added and the incubation temperature is increased to 42° C.[80,82,173]

Isolation, identification, and confirmation of *Campylobacter* isolates by cultural methods require plating enrichment broth samples after incubation onto selective agar plates. Typical colonies on selective agar media appear smooth, convex, and glistening with a distinct edge or flat, shiny, translucent, and spreading with an irregular edge. They are colorless to grayish or light cream and may range from pinpoint to 4 to 5 mm in diameter.[173] Growth of distinct colonies is facilitated by drying plates prior to inoculation and including in plate containers filter paper strips to which four drops of glycerol have been added.[165] Presumptive *Campylobacter* isolates can be observed using dark-field or phase-contrast microscopy for characteristic morphology and motility;[173] however, cells from cultures older than about 24 hours may appear coccoidal and nonmotile. Biochemical and growth parameter tests are used to further confirm an isolate as *Campylobacter*.[136] Although separation of *C. jejuni* and *C. coli* isolates may not be necessary in a food microbiology laboratory, the two strains may be separated by the hippurate hydrolysis test; *C. jejuni* is positive.[160]

Colonies of *Campylobacter* can be identified by commercially available latex agglutination tests such as those marketed by Integrated Diagnostics, Inc., Baltimore, MD; Mercia Diagnostics, Shalford, UK; and Becton Dickinson Microbiology Systems, Cincinnati, OH. Enzyme-linked fluorescent assay (ELFA) systems such as the VIDAS system (bioMerieux Vitek, Hazelwood, MO) provide fully automated qualitative detection of *Campylobacter* from a 24- to 48-hour enriched sample in about 70 minutes. Immunomagnetic separation methods coupled with polymerase chain reaction (PCR)-based detection systems are being developed for detection of *Campylobacter* from food samples.[44,127]

40.8.2 Typing Schemes

Typing of *Campylobacter* strains is particularly needed for epidemiological purposes. Typing methods can be divided into two main categories: those based on phenotypic characteristics such as heat-stable or heat-labile (HL) antigens[106,137] and those based on genotyping. Included in this latter category are restriction fragment length polymorphism (RFLP) of selected genomes such as done with ribotyping of other genomes,[119] bacterial restriction endonuclease DNA analysis (BRENDA), and pulsed field gel electrophoresis.

Phenotype-based Schemes

The most well developed typing schemes used in epidemiological studies are those based on the use of the soluble, thermostable lipopolysaccharide antigens that can be used in a passive hemoagglutination test,[103] and the use of thermolabile flagella antigens that can be used in a slide agglutination test.[106] More recently, phage typing schemes have been developed. Thus Grajewski et al.[66] originally described a set of 14 phage types that discriminated about 90% of the 255 human isolates tested. The number of phage types was expanded by Kaijser and Falsen,[97] who were able to discriminate 78% of the 301 isolates tested; a new phage typing scheme that claimed better discrimination and typability of campylobacters was described by Salama et al.[156] However, it is recommended that phage typing is used together with another typing method to discriminate confidently between isolates.

A further phenotypic assay involves the analysis of the OMP of campylobacters by sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE). Although good discrimination is possible, limitations of SDS-PAGE to discriminate between isolates have been reported also.[18,43,107] In addition, considerable technician time is required for such analyses, and interlaboratory reproducibility has been poor.

A biotyping scheme that is commercially available (MAST, Camp-BID, Mast Diagnostics, Merseyside, UK) distinguishes between the four enteropathogenic *Campylobacter* spp. and subdivides these into 55 groups.[22] The scheme is based on antibiotic-resistance patterns and limited biochemical assays and provides a four-digit code that indicates the species and subgrouping. It could be useful for laboratories not in need of the ultimate discriminatory capability by allowing tracking abilities with simplified technology and limited costs.

Genotype-based Schemes

A comparison of 10 methods for subgrouping *Campylobacter* strains based on genotyping was published in 1991.[134] The genotyping methods studied included multilocus enzyme electrophoresis (MEE), BRENDA, restriction digests of selected bacterial chromosomal DNA (ribotyping), and plasmid profile analysis; these methods are fully described in Chapter 64. The authors concluded that MEE, BRENDA, and ribotyping were the most sensitive methods and were capable of identifying 9 types among 22 strains. The authors observed that MEE and ribotyping had several advantages over the other methods because they measured relatively stable and significant chromosomal differences and were applicable to other species and genera. Hernandez et al.[75] analyzed 39 strains of campylobacters by ribotyping and confirmed these conclusions. Modification to the method by Patton et al.[134] employed use of the HaeIII enzyme to digest the isolated chromosomal DNA; on electrophoresis of the digest product, they were able to distinguish 32 different band profiles that allowed discrimination between the strains analyzed. Each ribotyping pattern comprised between 3 and 11 fragments of 1 to 10 kb.

A further genotyping scheme for *Campylobacter* has been described that entails probing the flagellin gene, *flaA*, for differences or similarities between strains.[119] The method uses PCR and RFLP.

40.9 CONTROL IN POULTRY OPERATIONS

Despite substantial effort by international researchers, contamination of domestic meat animals, especially poultry, continues to be a worldwide problem. When contaminated animals are presented for slaughter, the opportunity for spread of zoonotic pathogens during dressing of the carcass (particularly during defeathering and evisceration) is substantial, even under the best of conditions. Stern et al.[169] demonstrated that chicken carcasses become more contaminated with *C. jejuni* when broilers are moved from the farm to the processing plant. One hundred birds from 10 separate flocks were sampled at the farm by whole carcass rinse and another hundred carcasses were analyzed following transportation but prior to processing. Prior to transportation, an average of log cfu of 3.66 campylobacters per carcass were identified; following transportation, carcasses averaged log cfu of 7.11 of campylobacters per carcass. Prevalence was also affected: before transportation, only 6 of the 10 flocks were positive for campylobacters as determined by whole carcass rinse, while 9 were positive after transport. Procedures required to remove or kill this pathogen once it has become attached to carcasses and derived meat products would be likely to decrease the organoleptic quality of the meat. However, if means were developed to reduce the incidence campylobacters in the chicken gastrointestinal tract, then processed carcasses with reduced levels of the pathogen could be achieved. Concomitantly, the reduced incidence and level of campylobacter-contaminated poultry products would reduce consumer exposure and should result in diminished frequency of the human disease. The means whereby campylobacters are introduced into a flock of chickens has been difficult to determine and is still disputed, but once in the flock, the gastrointestinal tracts of most birds soon become colonized.[55,81,94,105,157,184] Campylobacters are not an essential part of normal poultry flora because birds can be brought to market without colonization. Pearson et al.[135] suggest the possibility of vertical spread of the organism from the hatchery; however, this remains controversial. Campylobacters normally cause no pathology or change in growth of the chicken; therefore, it is more accurate to refer to the habitation of the chicken intestinal tract by these organisms as a "colonization" rather than an infection. The primary incentive to poultry producers to preventing colonization, therefore, is to increase the human health attributes of the final product.

In one study of broilers at slaughter, 79% of the birds were colonized with campylobacters.[140] Flocks apparently vary in prevalence of colonization from none to 100%;[86,174] however, a prevalence of less than 100% could be due to the timing of sampling relative to the time when the organism was introduced to the flock. Not only is the prevalence of campylobacters in poultry high, but the levels of the organism on carcasses of fully processed chickens have been reported as up to 1.5×10^6 cfu per chicken.[76,85]

Dolby and Newell[45] reported that by intraperitoneal vaccination of female mice with a strain of *C. jejuni* before mating, the dams conferred immunity to their young, demonstrated by oral challenge 4 to 6 days after birth with the homologous strain; they were unable to demonstrate protection against a heterologous strain. Abimiku and Dolby[1] confirmed these observations and also reported that the mouse pups required the consumption of immune milk at and after the time of challenge to resist colonization by *C. jejuni*. These two reports strongly suggest the possibilities of vaccine administration to prevent the colonization by *Campylobacter*.

In the UK, epidemiological investigations linked many sporadic cases of *Campylobacter* infection to chickens from one farm.[135] Water was suggested to be the principal source for the spread of the organism on the farm, based on detection by filtration and fluorescent antibody techniques. It was suggested also that scrubbing the water storage tanks with quaternary ammonium compound disinfectant diminished the presence of campylobacter in chickens.

Rollins and Colwell[149] demonstrated that *C. jejuni* can exist in a viable, nonculturable form (VBNC). Cells in this form were able to take up radio-labeled amino acids and maintained intact outer membranes, but were unable to produce colony-forming-units on selective campylobacter media. Stern et al.[172] grew six poultry isolates of *C. jejuni* overnight on agar plates, suspended the growth from these at 10^8 cells ml^{-1} in phosphate-buffered saline, and maintained the suspensions at 4° C; at weekly intervals, the number of viable organisms was determined on Brucella-FBP agar (a nonselective medium). When the organisms were no longer detectable by direct plating on Brucella-FBP agar (4 to 7 weeks), 50 ml of each of the original suspensions were cultured by enrichment and this enrichment procedure was repeated 2 weeks later. At neither time were any of the six strains successfully cultured. Once the VBNC status of the cultures was determined, day-old chicks (n = 11 to 20) were orally gavaged with 0.2 ml of each of the suspensions. The birds were placed in isolation units and segregated according to challenge culture. An additional isolation unit was used to house unchallenged control chicks. One week after challenge, the birds were sacrificed and the cecal contents were cultured directly on Campy-Cefex selective agar. Four of the *C. jejuni* strains colonized low numbers of the chickens (5 of 79), while the other two isolates did not (0 of 30). None of 18 control chicks were colonized. The original and recovered strains were analyzed by BRENDA and HL antigen typing; they were indistinguishable. The discovery of a colonizing but nonculturable form of *Campylobacter* provides a potential explanation for sources of the bacterium in broilers. The chicken-passaged, previously nonculturable materials yielded *Campylobacter* that were indistinguishable from the original isolate of *Campylobacter*.

40.10 CONCLUDING REMARKS

Although campylobacters are apparently fragile organisms easily killed by all commonly applied methods used to decontaminate foods, they, and in particular *C. jejuni*, are the leading cause of bacterially induced human gastroenteritis. A possible reason why such a fragile bacterium can cause so many cases of gastrointestinal illness is its low infective dose combined with its widespread occurrence, often in large numbers, on poultry carcasses, providing opportunity for postcooking recontamination of poultry and cross-contamination via utensils and working surfaces onto other foods. A terminal pasteurization step (eg, irradiation or heat pasteurization) applied under controlled conditions at the processing plant, seems to be the best means currently available of preventing campylobacteriosis. It is incumbent on the industry and researchers to continue to explore strategies that will reduce levels of consumer exposure. As this organism is incapable of multiplying on foods at temperatures below 30° C, controlling the colonization of the intestinal tract in farm animals (eg, by vaccination) or finding ways to limit carcass contamination could accomplish this ambitious goal.

41.1 INTRODUCTION

The species *Clostridium botulinum* comprises a group of Gram-positive, spore-forming, anaerobic bacteria that form a powerful neurotoxin. Botulism in adult humans is caused by the consumption of food containing toxin produced by growth of *C. botulinum*. Sometimes the organism contaminates deep wounds where it multiplies and forms toxin, which spreads from the wound to cause the characteristic symptoms of botulism (wound botulism). Infant botulism, which usually affects infants less than 35 weeks old, is caused by ingestion of spores followed by establishment of the organism in the intestinal tract where it multiplies and forms toxin. Very rarely botulism associated with colonization of the gut has been reported in an adult who has undergone surgery for intestinal disease.[50,197]

C. botulinum was first isolated in 1897; subsequent isolates were shown to form neurotoxins that differed antigenically and were therefore differentiated into several types: A, B, C, D, E, F, and G. Based on their physiological properties, and later confirmed by their phylogenetic relationship, strains of *C. botulinum* were classified into four groups (Table 41–1); this grouping does not correspond with the differentiation according to the antigenicity of the neurotoxins. The use of a single species name for bacteria in Groups I to IV does not reflect the true phylogenetic relationships of these bacteria or their physiological properties.[54] It is retained because of the importance of these bacteria as pathogens in humans, animals, and birds, and the confusion that would be caused by renaming the bacteria in accordance with their phylogenetic and physiological similarity.[232]

Although many strains of *C. botulinum* produce toxin of a single antigenic type, some strains produce two types of toxin, usually a major amount of one toxin and a minor amount of the other.[128] Such strains have been designated Af (indicating the major and minor toxin respectively), Bf, Ab, and Ba. In 1979–1980, a case of infant botulism in New Mexico was attributed to an organism that produced type F toxin[145] and was subsequently identified as a strain of *C. baratii*[117]and two cases of infant botulism in Italy in 1984 were attributed to bacteria that resembled *C. butyricum* but formed type E toxin;[15,196] the identity of these organisms as *C. baratii* and *C. butyricum*, respectively was confirmed by study of their DNA relatedness.[309] In 1987 a further strain of *C. baratii* that formed type F toxin was isolated from an adult suffering type F botulism, probably caused by intestinal colonization,[197] and an outbreak of foodborne botulism in China in 1994, which affected six people, was attributed to a strain of *C. butyricum* that formed type E toxin.[202]

A history of developments in relation to botulism was outlined by Smith and Sugiyama[292] and Hauschild[127] and is summarized and updated in Exhibit 41–1. Early outbreaks associated with meat and poultry products were summarized by Tompkin.[327]

The term "botulism" is derived from the Latin *botulus* (sausage) and the name was given to a disease, reported mainly in Central Europe in the 1800s, that was generally associated with sausage consumption. *Clostridium botulinum* was first isolated by van Ermengem in 1897 from raw, salted ham that caused an outbreak of the disease in Belgium and from the spleen of a victim. Later the isolates were lost, but reports of the properties of the organism suggest that it would now be classified as nonproteolytic *C. botulinum* producing type B toxin. In early studies the name *C. botulinum* was used for nonproteolytic strains and *C. parabotulinum* for proteolytic strains. This distinction

Table 41–1 Groups of *Clostridium botulinum*, Toxins Formed and Main Species Affected

Group	*Toxins Formed*	*Main Species Affected*	*Examples of Main Food or Feed Implicated*
I (proteolytic)	A	Humans	Canned, low-acid foods (mainly home-canned)
	B	Humans Cattle; horses	Canned, low-acid foods (mainly home-canned) Hay or silage that may be contaminated by carcasses of small animals
	F	Humans	Very few cases reported
II (nonproteolytic)	B	Humans	Some outbreaks due to home-cured hams
	E	Humans Salmonid fish	Fish products Cannibalism of dead fish
	F	Humans	Very few cases reported
III	C (C_1 and C_2)	Birds, particularly waterbirds, also farmed chickens and pheasants	Carcasses of vertebrates and invertebrates
		Cattle, horses, mink, and other animals	Hay, silage, or poultry litter that may be contaminated with carcasses of small animals
	D	Cattle, sheep	Carcasses or bones of small animals
IV	G	Lack of evidence

was based on the ability of the bacteria to digest cubes of coagulated egg white, cooked meat particles and casein; proteolytic and nonproteolytic strains showed a marked quantitative difference in this ability.[116] Subsequently the name *C. botulinum* was adopted for both of these groups and for Group III and later Group IV organisms, for which the name *C. argentinense* was proposed later.[310]

Human botulism worldwide is almost always caused by toxins of types A, B, and E.[124] Fewer than 10 incidents of foodborne type F botulism in humans have been documented, and there are reports of two incidents attributed to organisms producing type C toxin and one to an organism producing type D toxin.[124] Botulism occurs in many types of animals other than man and is usually due to Group III organisms producing type C or D toxin.[292] Proteolytic *C. botulinum* forming type B toxin has caused outbreaks of botulism in cattle and of toxicoinfectious botulism in horses, which are reported to be particularly susceptible to type B toxin. The majority of outbreaks of botulism in birds, particularly water birds, have been caused by Group III organisms producing type C toxin, but some outbreaks due to organisms forming type E toxin have been reported, probably due to the consumption of toxic fish.[77]

Since 1980 the medical use of purified botulinum toxin type A for treatment of hyperactive muscle disorders has been investigated; use of the toxin for certain types of treatment was licensed in the United States (US) in 1989 and in the United Kingdom (UK) in 1991.[237,271]

41.2 TAXONOMY AND PROPERTIES OF THE ORGANISMS

41.2.1 Taxonomy

Clostridium botulinum is differentiated into four groups on the basis of physiological characteristics that are shown, together with those of neurotoxin-forming strains of *C. butyricum* and *C. baratii*, in Table 41–2.

Both DNA-DNA hybridization studies and 16S-rRNA sequence analysis have shown that while strains within a phenotypic group are highly related, regardless of the toxin type produced, the four phenotypic groups correspond to four phylogenetically

Exhibit 41–1 Milestones in Relation to Botulism

Year	*Notes*
1793	Outbreak of botulism recorded in Wildbad associated with consumption of blood sausage. Thirteen people were ill and a further six died.
1815–1828	Kerner documented 234 cases of botulism predominantly associated with blood and liver sausage.
1895–1897	An outbreak of botulism in Belgium affected 23 of a group of 34 musicians; 3 died and 10 nearly died. The outbreak was associated with consumption of homemade ham. van Ermengem isolated a toxigenic bacterium (*Bacillus botulinus*) from the ham and from the spleen of a man who died. This was probably a nonproteolytic strain that produced type B toxin.
1904	Landman isolated a toxinogenic bacterium from salad, made with home-canned beans, that caused an outbreak of botulism in Darmstadt, Germany. The toxin was later designated type A.
1910	Leuchs reported that the above strains produced serologically distinct neurotoxins.
1919	Burke divided American isolates into those that produced type A and others that produced type B toxin. van Ermengem and Landman strains were no longer available for testing.
1922–1925	Organisms that caused a paralytic disease of chickens in the US and bulbar paralysis of cattle in Australia were designated as producing type C toxin.
1928–1929	An organism isolated from an outbreak of paralytic disease (lamsieke) in cattle in South Africa was shown to produce a toxin designated as type D.
1934–1937	Hazen in the US and Kushnir in Russia separately isolated *C. botulinum* from fish associated with human botulism.
1936–1937	Hazen's and Kushnir's strains were shown to produce an antigenically similar toxin designated type E.
1943	Wound botulism was first reported in the US.
1946	Lamanna crystallized type A toxin and showed that it was a protein.
1953	*C. botulinum* was defined as species designation for all bacteria known to form botulinum toxin, and therefore able to cause botulism in man or animals; the term *C. parabotulinum* was eliminated.
1958–1960	A new strain (proteolytic, Langeland) later shown to form type F toxin, was implicated in an outbreak of botulism that affected four people on the island of Langeland and was due to homemade liver paste.
1965–1966	Nonproteolytic strains that produced type F toxin were isolated from marine sediments and from fish.
1970	A bacterium described as producing as type G neurotoxin was isolated from soil in Argentina.
1970	A strain was described that produced two toxins (types A and F). Other strains that produce two toxins have been isolated since.
1976	Infant botulism was recognized. A case in 1975 was recognized retrospectively. Strains isolated were proteolytic and produced type A or type B toxin.
1980–1982	Infant botulism due to a bacterium producing type F toxin was reported; the bacterium was later identified as *C. baratii.*
1981	A strain of *C. botulinum* that formed type B as the major toxin and a minor amount of type A toxin was isolated from a case of infant botulism. A further isolate from a case of infant botulism produced type B as the major toxin and a minor amount of type F toxin.

continues

Exhibit 41–1 continued

Year	*Notes*
1986	*Clostridium butyricum* strains that produced type E botulinum toxin were isolated from cases of infant botulism.
1990	*C. botulinum* producing type C toxin was reported as the cause of infant botulism in Japan.[228]
1992	*C. botulinum* type B toxin was reported to be a zinc endopeptidase.[273]
1992	Clinical trial of Human Immune Globulin for treatment of infant botulism was started.[12]
1994	An outbreak of foodborne botulism in China was attributed to a strain of *C. butyricum* that produced type E toxin.[202]

distinct groups.[54] Strains from Groups I and II show a low relatedness even though they may produce the same toxin type. The distinction between Groups I to IV is strong enough to merit the creation of four species, were it not for the desire for practical purposes to retain the name *Clostridium botulinum* for these groups.

It is convenient to refer to strains of *C. botulinum* as "*C. botulinum* type A," etc. depending on the toxin formed, but it would be more correct to use the term "*C. botulinum* toxin-type A," as the "type" refers to the antigenic type of the toxin formed, not to properties of the organism itself. Because both proteolytic and nonproteolytic strains can form type B and type F toxins, in referring to a strain as type B or type F there is a need to make clear whether the strain belongs to Group I proteolytic or Group II nonproteolytic *C. botulinum.*

41.2.2 Properties of Bacteria That Form *Clostridium botulinum* Neurotoxin

The *C. botulinum* group of bacteria are anaerobic, motile, spore-forming rods 0.5 to 2.0 μm wide and 1.6 to 20 μm long.[42] Because botulism in humans is caused predominantly by Group I and Group II strains, this chapter will concentrate on these organisms. Group I organisms are actively proteolytic (ie, they are able to digest native proteins and rapidly break down particles of meat in meat media, cubes of coagulated egg white, and casein).[116] They also rapidly degrade the derived protein, gelatin. Group II organisms do not degrade these native proteins but liquefy gelatin, although less actively than Group I strains. Isobutyric acid, isovaleric acid, and phenylpropionic acid are formed as degradation products of the amino acids valine, isoleucine/leucine, and phenylalanine, respectively, by Group I but not Group II strains (Table 41–2).[42] The minimum temperature for growth of these bacteria is of major importance: Group I strains are unable to multiply at temperatures of 10° C and lower, whereas Group II strains can multiply at temperatures as low as 3.0 to 3.3° C.[79,80,112,276] The spores of Group I strains are much more heat-resistant than those of Group II strains (Section 41.7).

41.2.3 Properties of Spores of *Clostridium botulinum*

Studies of the physiology of sporulation have shown marked differences between Group I and Group II *C. botulinum.*[292] The spores of all groups are subterminal; those of Group I strains swell the sporangium markedly while those of Groups II and III strains do so to a lesser extent. The structure of the spores is similar essentially to that of other species of *Clostridium* and of *Bacillus.* In many cultural conditions, spores of Group I strains are retained within the sporangium for a prolonged period,[304] and even after harvesting and refrigerated storage in aqueous suspensions for several months the majority of mature, phase-bright spores may still be within a sporangium. In contrast, when spores of Group II strains are formed, the sporangium appears to be lysed within a few days, leaving the mature spore free of the sporangium.

Spores of some Group II, type E strains are contained within an exosporium that may be thin and membranous, thicker with a hexagonal pattern, or thicker and homogeneous.[143,144] In general, the function of the exosporium is unknown. Spores of some of these type E strains also carry a large number of appendages approximately 20 nm in diameter and up to 350 nm long, each appearing to be tubular with a hemispherical cap (Figure 41–1). These appendages do not appear to be associated with motility or attachment or to play a role in spore germination and outgrowth and have no known function.[292] Spores of the Group I strain 78A had a multilayered exosporium and were usually within a sporangium, whereas those of the Group II strain 17B were covered by an open-ended, sheath-like exosporium and usually were present as free spores.[304]

41.3 CHARACTERISTICS OF BOTULISM

Foodborne botulism is caused by ingestion of food containing toxin preformed during growth of the bacteria. Onset of symptoms usually occurs within 12 to 36 h but can occur within 2 h or after as long as 8 days.[292] Nausea and vomiting often precede other symptoms and probably are not caused by botulinum toxin but by other substances produced by *C. botulinum* during its growth in food.[292] The neurotoxin first affects neuromuscular junctions of the head and neck, preventing the passage of stimuli from motor nerves to muscles and resulting in double vision, inability to focus, drooping eyelids, thickness of speech, and inability to swallow or to speak clearly. As the disease progresses, there is increased muscle failure until muscles needed for breathing (the diaphragm and intercostal muscles) or the cardiac muscles fail and death follows. Foodborne botulism has been confused with other diseases including Guillain-Barré syndrome and my-

asthenia gravis, as well as with the effects of other food-poisoning bacteria.

In the early 1900s, 71% of cases of botulism in the US were fatal, but by the 1970s this had been reduced to 15%.[125] The greatest factor in this improvement is said to be improvement in supportive care. A high proportion of patients with foodborne botulism need respiratory support. In the US, treatment by intravenous infusion with therapeutic, trivalent botulism antitoxin is recommended immediately after diagnosis is made, without waiting for laboratory confirmation. By the time clinical symptoms of botulism are present, toxin has bound irreversibly, blocking release of acetylcholine, and antitoxin will only neutralize circulating toxin that is not bound irreversibly to receptors. The antitoxin is prepared from horse serum and its use involves the risk of hypersensitivity reactions. In 268 patients treated with antitoxin in the US between 1967 and 1977, 9% suffered adverse reactions, 2.6% developed urticaria, 1.9% developed anaphylaxis, and 3.7% developed serum sickness.[125] According to some reports, guanidine given orally may be useful in the treatment of botulism;[265] it increases the endplate potential by increasing the amount of acetylcholine released at nerve endings.[292]

Infant botulism was described first in California in 1976 but cases have been reported since in many countries. The majority of reported cases have been caused by bacteria producing type A or B toxin, but organisms producing types E and F toxin have occasionally been implicated; a single report implicated type C toxin. Infant botulism usually occurs in infants less than 35 weeks old and is caused by ingestion of spores of the causative organism; there is evidence that between 10 and 100 spores can cause the infection.[206,292] Numbers of *C. botulinum* as high as 6.0×10^8 colony forming units (cfu) g^{-1} have been reported in the feces of infants with infant botulism.[345] The disease is characterized by constipation, generalized weakness, and other neurological symptoms.[206] This illness is restricted to young infants probably because the intestinal microflora in these infants is insufficiently established to prevent colonization by *C. botulinum* and related organisms. Healthy infant mice are susceptible to colonization by *C. botulinum* spores for a very limited period of their life. Adult germ-free mice and adult mice treated with antibiotics are susceptible also, but become resistant when the mice acquire intestinal microorganisms that are present in normal, adult mice.[32]

In treating cases of infant botulism, equine antitoxin is avoided because of the risk of adverse reactions and of sensitizing the child at such an early age. The use of antibiotics is also not recommended because of the risk that the resulting lysis of the bacteria may result in an increased release of botulinum toxin in the intestine. To test an alternative treatment for infant botulism, a randomized, placebo-controlled trial of human botulism immune globulin (BIG) was started in California in 1992.[12] This study used antibody preparations from the serum of immunized human volunteers (immunized because they were involved in laboratory work on *C. botulinum*). Results from this study showed that intravenous treatment with human BIG was a safe and effective treatment for infant botulism due to proteolytic *C. botulinum* types A and B. For example, the mean hospital stay was reduced from approximately 5.5 weeks to approximately 2.5 weeks, and the mean hospital cost was reduced from $127,900 to $59,200.[13]

The few reported cases in which *C. botulinum* appears to have become established as an intestinal infection in adults[50,197,292] may have occurred when competing bacteria in the normal intestinal microflora have been suppressed by treatment with antibiotics.

According to Smith and Sugiyama,[292] wound botulism is caused only by Group I strains of *C. botulinum*, and the period between infection of the wound and development of symptoms tends to be relatively long, between 4 and 14 days. This incubation period presumably depends on the time needed for conditions in the wound to become suitable to allow growth of the organism and formation and spread of the toxin.

41.4 MECHANISM OF PATHOGENICITY

41.4.1 Structure of Neurotoxins

The major factors responsible for pathogenicity of *C. botulinum* are the toxins (BoNTs). These toxins are neurotoxins, with the exception of C_2 which is of a different type and is cytotoxic.[214,274,292] BoNTs are formed initially as single-chain polypeptides with a molecular weight of about 150 kDa, corresponding to between 1,251 and 1,297 amino acids,[249] and relatively low toxicity[62] and are thought to be released by cell lysis. The single-chain form (protoxin) is converted to a di-chain form (a process termed "nicking"[62]) by extracellular bacterial protease or by an added protease, such as trypsin, to form a molecule consisting of a light chain (L chain ~ 50 kDa) and a heavy chain (H chain, ~100 kDa) linked by a disulphide bond. The bacterial protease and trypsin may attack the same bond or closely associated bonds.[62] Nicking is accompanied usually by activation of the toxin, giving an increase in toxicity of up to 500-fold. Nicking appears to be essential but not sufficient for full activation of toxin[62,286] and there is evidence that conformational changes may be involved also in activation.[62,128] In cultures and in foods, the BoNT may be present either as the single-chain (un-nicked) or as the di-chain form, or as a mixture of the two, depending on the physiology of the organism, the time of incubation,[62] and conditions in the culture or food. The disulphide bridge can be severed by treatment with dithiothreitol, resulting in two nontoxic components. Growth of strains of Group I, proteolytic *C. botulinum* is accompanied usually by the production of proteases that activate the protoxin to highly active toxin, but in the case of Group II, nonproteolytic organisms, the toxin is formed mainly in the poorly active, single-chain form, and in laboratory tests trypsin must be added to activate the toxin in order to demonstrate the potential toxicity.

Toxins of the same type formed by different strains of *C. botulinum* are not necessarily identical.[124] This is shown by the fact that their reactions with a single antitoxin may differ quantitatively (Section 41.8.3). Studies of the nucleotide sequences of representative strains of each of the seven toxin types have also shown differences between the toxin genes from strains producing toxin of the same antigenic type, indicating differences between the amino acid sequences of toxins of the same type from different strains.[54,211]

BoNTs occur in complexes of four molecular sizes, in three of which the toxin is associated with nontoxic proteins (Table 41–3).[128] The M and L forms, referred to as progenitor toxins, are the forms usually found in foods. Progenitor toxins are, in general, more stable at high temperatures and low pH than purified derivative toxin, and their greater stability may prevent or reduce breakdown of toxin in the stomach. RNA is associated also with some toxin complexes but has no known role in activity or stability.[271]

The nature of the food or the culture medium in which growth of the bacterium occurs and the presence of metal ions can affect the size of the toxin complex formed and hence the stability of the toxin. During incubation in foods at 30° C for 7 days, type A strain 62A formed the more stable 16S (L) and occasionally 19S (LL) toxin in string beans and 16S complex in mushrooms, whereas mainly 12S (M) toxin was formed in tuna occasionally with 16S toxin in pork.[311] The proteolytic type B strain Okra formed the 16S complex in all these foods but also produced the less stable 12S complex in tuna and in pork. Type E strain German sprats was tested in mushrooms and tuna, where it only formed 12S complex, and the proteolytic type F strain Langeland formed only the 12S complex in these four foods. Uncomplexed, derivative toxin was not detected. The addition of 5 mM $FeSO_4$ or 5mM $MnCl_2$ to string beans resulted in formation of the 12S rather than the 16S complex by the type A strain, and the addition of 10 mM $FeSO_4$ or 10 mM $FeCl_2$ resulted in formation of the 12S complex rather than the 16S complex by the type B strain.

At pH values below 6.5, the toxin complexes appear to be stable, but if the pH is raised above 7.5 the complexes dissociate, liberating the free neurotoxin. This phenomenon is used in purification of the BoNT.[128,283] The dissociated complexes re-form spontaneously if the pH is lowered. The neurotoxin can be separated from nontoxic components by ion exchange chromatography.

Studies of the neurotoxin genes and the amino acid sequences of toxins of strains representing each toxin type have shown that the L chain is composed of about 450 amino acid residues and contains a zinc-binding site;[275] in representative strains of types A, B, and F, there is evidence that one atom of zinc is bound to the L chain. The crystal structure of type A botulinum neurotoxin has been reported recently.[174]

41.4.2 Control of Neurotoxin Formation

There is some uncertainty about the location of genes controlling BoNT production in Group I and II *C. botulinum*. Because it has not been possible to demonstrate the involvement of either a phage or a plasmid, it has been assumed that these genes are located on the chromosome, but there is a possibility that in some Group I strains the toxin gene is part of a prophage genome present in the chromosome.[211] About 50% of type A strains that formed BoNT/A contained an unexpressed gene for BoNT/B production.[57,96] The genes for BoNTs C_1 and D are present in pseudolysogenic phages, whereas the gene for production of C_2 toxin appears to be located on the chromosome. Nontoxigenic derivatives of type C and type D strains of *C. botulinum* were indistinguishable from each other and from nontoxigenic strains of *C. novyi* type A, and a strain of nontoxigenic *C. botulinum* type C could be converted back either to toxigenic *C. botulinum* type C or type D or to *C. novyi* type A by infection with a bacteriophage carrying the gene for the appropriate toxin.[78] The gene for BoNT/G is reported to be on an 81-MDa plasmid.[355] The location of the toxin genes in toxinogenic strains of *C. butyricum* and *C. baratii*

Table 41–3 *C. botulinum* Neurotoxins and Toxin Complexes

Complex	*Approximate Mass*	*Components*	*Toxin Types*
S "derivative toxin"	150 kDa (7S)[a]	Single chain (heavy{H} chain, ~100 kDa linked to light{L} chain, ~ 50 kDa)	
M "progenitor toxin"	300 kDa (12S)	**S** + nontoxic nonhemagglutinin (NTNH)	A,B,C,D,E,F
L "progenitor toxin"	450–500 kDa (16S)	**M** + hemagglutinin (HA)	A,B,C,D,G
LL	900 kDa (19S)	Probably a dimer of **L**	A

Sakaguchi, *Clostridium Botulinum* Toxins, *Pharmacology and Therapeutics*, Vol. 19, pp. 165–194, © 1983, Elsevier Applied Science.

has not yet been shown definitively.[211] During repeated culture in the laboratory, some strains of *C. botulinum* gradually tend to lose the ability to form high concentrations of toxin and good production of toxin tends to be associated with poor sporulation.[271]

41.4.3 Mechanism of Action of Neurotoxins

The BoNTs act primarily at peripheral cholinergic synapses blocking release of the neurotransmitter acetylcholine; adrenergic systems are affected also, but the dose required to inhibit the release of noradrenaline is much higher than that needed to inhibit release of acetylcholine.[128] Four steps in the action of the BoNTs have been recognized:[274]

1. binding of the heavy (H) chain of the toxin to a specific receptor on the surface of the presynaptic membrane of the motor neuron
2. internalization of the toxin-receptor complex by endocytosis resulting in the formation of endocytic vesicles
3. acidification of the lumen of the endocytic vesicle by a proton-pumping ATPase leading to a conformational change in the toxin, which then inserts into the lipid bilayer of the vesicle membrane; the light (L) chain is then translocated across the membrane of the endocytic vesicle
4. the L chain is freed in the cytosol of the motor neuron by reduction of the interchain disulphide bond, and by means of its zinc-endopeptidase activity, it cleaves protein components of the neurotransmitter-containing synaptic vesicle docking/fusion complex.

Cleavage of one of the proteins within this docking/fusion complex prevents binding of the acetylcholine-containing synaptic vesicles and consequently prevents the release of neurotransmitter and leads to flaccid paralysis of muscle. Each type of neurotoxin cleaves a specific protein involved in neurocytosis. BoNT/B, BoNT/D, BoNT/F, and BoNT/G attack VAMP (synaptobrevin), a protein located on the membrane of the neurotransmitter-containing synaptic vesicle, whereas BoNT/A, BoNT/C, and BoNT/E cleave proteins of the presynaptic membrane, BoNT/A and BoNT/E cleaving SNAP-25 (synaptosomal-associated protein of 25 kDa) and BoNT/C cleaving syntaxin.[274] Each of these toxins is reported to cleave a different, specific peptide bond.[224,274] BoNT/C may also cleave the carboxyl terminus of SNAP-25.[237]

Unlike the other botulinum toxins, toxin C_2 does not have a covalent bond between the L and H chains. It is not neurotoxic but has a cytotoxic effect, which appears to result from its ability to ribosylate actin and disorganize the microfilament network in cells.[128]

41.4.4 Lethality of Neurotoxins

According to Smith and Sugiyama,[292] when assayed by parenteral administration (intraperitoneal, (i.p.) or intravenous, (i.v.) injection), the specific toxicities of the purified, fully activated neurotoxins (S toxins) of the several toxin types range from about 1×10^7 to just over 1×10^8 mouse LD_{50} mg^{-1} protein, equivalent to one mouse i.p. LD_{50} per 0.1 to 0.01 ng protein. The specific toxicities of the bimolecular complex (M complex) and the trimolecular complex (L complex) by parenteral injection are about one half and one third of this, respectively. The specific toxicity of high-quality, crystalline type A toxin complex (900 kDa) should be 3×10^7 mouse i.p. LD_{50}

(± 20%) per mg[271] equivalent to one mouse i.p. LD_{50} per 0.033 ng protein.

Oral toxicity is only a fraction of i.p. toxicity and because complexes are much more stable than the purified toxin, the M and L complexes are much more toxic orally than the S toxin. The estimated minimum amount of toxin needed to cause botulism in humans is based on evidence from incidents of foodborne botulism in which the complexing of toxin in the food was not known.[292] In one case it was estimated that death of a 104 kg man resulted from the consumption of an amount of cheese containing about 3,500 mouse minimum lethal doses (i.p.) of type B toxin.[205] In general, data from cases of botulism in humans following the consumption of food containing toxin indicate that symptoms, and occasionally death, may be caused by as little as 3,000 mouse i.p. LD_{50};[271] this is approximately equivalent to 30 to 100 ng of botulinum toxin depending on the size of the toxin complex.

It has been reported that botulism in humans caused by type B toxin is less severe than that caused by type A toxin. From a study of 309 cases of adult botulism in the US between 1975 and 1988, it was concluded that type A botulism was most severe, as measured by the need for intubation to support respiration, while type E was associated with the shortest incubation periods.[348] No differentiation was made between illness caused by type B toxin produced by proteolytic *C. botulinum* and that produced by nonproteolytic *C. botulinum.* In a study of five strains that produced type B toxin and two that produced type A, all of which formed both M and L toxin complexes in culture medium, purified L toxin from proteolytic type B strain Okra showed much higher oral toxicity in mice than L toxin from the remaining type B and type A strains, whereas the i.p. toxicities were similar.[229] Experiments indicated that the unusually high oral toxicity of the type B toxin from the Okra strain was due to the nontoxic component of the complex and was probably a function of the molecular conformation of the complex.

41.5 INCIDENCE OF *CLOSTRIDIUM BOTULINUM* IN THE ENVIRONMENT AND IN FOODS

41.5.1 Dependence of Results on Methodology

Surveys of the incidence of *C. botulinum* in the environment have been made since the 1920s. Because of the difficulties inherent in detection and isolation of these bacteria, methods used in some of the surveys were subject to various limitations. The conditions optimum for enrichment and isolation of proteolytic, Group I organisms often are not favorable for nonproteolytic, Group II bacteria. For example, the use of heat treatment of samples at 80° C for 10 min to inactivate competing, vegetative bacteria is valuable for isolation from spores of proteolytic *C. botulinum*, but would probably inactivate spores of nonproteolytic strains; treatment of enrichment cultures with ethanol has proved a successful alternative for these.[292] Culture at 35° C is suitable for isolation of proteolytic strains whereas a lower temperature (eg, 26° C) is recommended for isolation of nonproteolytic strains.[299] In many studies, although the type of toxin has been determined, the properties of the organism were not reported, eg, for type B toxin it is not reported whether the bacterium was proteolytic or nonproteolytic.

Growth and isolation of *C. botulinum* can be prevented by competing microorganisms, including *C. perfringens* and *C. sporogenes*, and also by the presence of bacteriophages and bacteriocins (boticins).[165,292] Some samples of sediment from the Fox River in the US were highly inhibitory to Group II *C. botulinum* type E and it was necessary to add 10^6 spores of this bacterium to 1 g of sediment before type E toxin could be detected in culture.[312] The inhibitory effect was due probably to bacteriocins produced by nontoxinogenic Group II *C. botulinum.* Filter-sterilized trypsin can be added to the culture medium to inactivate bacteriocins. Failure to add trypsin to the medium to inactivate bacteriocins or failure to add lysozyme to enable recovery of heat-damaged spores (Section 41.7.3) may lead to failure to detect spores of Group II, nonproteolytic *C. botulinum.* In detecting the presence of toxin produced by Group II, nonproteolytic organisms, treatment of cultures with trypsin to convert the single-chain toxin to the toxic, di-chain form is important for the detection of activity by injection into mice (Section 41.8.2).

In attempts to detect and isolate *C. botulinum* from the environment or foods, it is important, therefore, to assess the adequacy of the method or methods used, by demonstrating that strains of all relevant groups of *C. botulinum* can be isolated following addition of low numbers to test samples from which the organism could not be isolated previously.[312] The detection of *C. botulinum* in a survey will depend also on the size and number of the samples tested. In considering reports of the incidence of *C. botulinum*, therefore, the possible limitations of the methodology used need to be taken into account. In the following discussion it is not practical to review the methodology in each case, but despite this limitation the surveys make it clear that there can be a relatively high incidence of the organism in some environmental samples and foods.

41.5.2 Incidence in the Environment

Quantitative information on the incidence of *C. botulinum* spores in soil and sediment in many parts of the world was summarized by Dodds.[71] The reported incidence of the organism generally is much higher in samples of wet sediments and shoreline samples than in inland soils. In samples of soil and sediment from North America, the percentage of positive samples ranged from 1% in samples of Gulf of Maine sediment to 91% in samples of Washington Bay sediment. The highest estimated number of *C. botulinum* spores was a most probable number (MPN) of 1280 g^{-1} in Green Bay (US) sediment, and in the majority of sediments the organisms isolated most frequently produced type E toxin.[71] In soil samples from the western US, 29% were positive and the majority of isolates (62%) formed type A toxin, whereas in the eastern US, 19% of samples were positive and the majority of isolates (64%) formed type B toxin;[291] while most of the strains producing type B toxin formed the protoxin rather than the active toxin, which usually is considered typical of nonproteolytic *C. botulinum*, according to Hauschild[127] the majority of the North American type B strains are proteolytic.

In surveys in Europe, the reported incidence of *C. botulinum* spores ranged from 0 in samples of Iceland coast sediment and Faroe islands soil to 94% (MPN 2500 kg^{-1}) in samples of sediments in the Netherlands, 98% (MPN 76 kg^{-1}) in samples of sediment from the Norfolk Broads in the UK and 100% in samples of sediment from the Baltic sea (MPN>320 kg^{-1}), the Skagerrak Kattegat sediment (MPN>780 kg^{-1}), and the Sound sediment off the coast of Scandinavia (MPN>1750 kg^{-1}). In the sediments from the Norfolk Broads and from the Netherlands, similar proportions of organisms forming type B, type C/D, and type E toxins were detected, whereas in the other sediments with 100% positive samples, only strains forming type E toxin were detected. Tests using the polymerase chain reaction (PCR) to detect neurotoxin genes indicated that of 110 samples of sediment from the Baltic sea and from the Finnish mainland, 81% of samples of Baltic sea sediment and 61% of samples of freshwater sediment contained *C. botulinum* type E at average MPNs of 940 and 370 spores kg^{-1} respectively.[138]

Surveys in Asia showed that the percentage of positive samples ranged from 0 in samples of sediments from the coast and the Mekong river in Thailand to 75% (MPN 25,000 kg^{-1}) (47% type A, 32% type B, 19% type C/D) in samples of Sinkiang soil in China and 78% (MPN 153 kg^{-1}) in soil from Taiwan (34% type A, 37% type B, 20% type E). A survey for nonproteolytic *C. botulinum* in river soils in Japan showed the presence of type E toxin-producing organisms in up to 82% of samples from some regions and of type B toxin-producing organisms in up to 9% of samples.[350]

In samples from other parts of the world, the reported incidence of *C. botulinum* spores ranged from 0 in samples of soils and sediment from the South Orkney Islands and Brazilian pasture land soil to 34% (mainly type A) in samples of Argentina soil, 35% (mainly type A) in cultivated soil in Brazil, and 55% (all type C/D) in sediment in Auckland, New Zealand.

The isolation of *C. botulinum* from soils is influenced probably by the fact that the estimated numbers of spores of *C. botulinum* in soils are much lower than those of some other *Clostridium* spp. The numbers of *C. pasteurianum*-like bacteria in soils varied between 10^3 and 10^4 g^{-1} dry soil while numbers in the rhizosphere of mangel crops reached 1.4×10^6 g^{-1}.[163] Soils from the Midlands in the UK and from forest and grassland soils in Ghana contained 10^3 to 10^5 N_2-fixing clostridia per g of air-dried soil.[199,200] In six UK Midland soils, counts of 10^4 to 10^6 clostridia spores g^{-1} were found, one of the most common species being *C. perfringens;*[101] and *C. perfringens* type A at levels of 10^3 to 10^4 cfu g^{-1} has been isolated from most of the soil samples examined.[173]

41.5.3 Incidence in Foods

Evidence from Outbreaks of Botulism

Some indication of the widespread occurrence of *C. botulinum* in foods is given by the range of foods that have been implicated in outbreaks of botulism. In addition to fish, meat, and vegetable products, which are the main types of food implicated, and honey, which is associated with infant botulism, unexpected types of food have been implicated, including cheese, hazelnut yogurt, peanuts, and black olives (Section 41.6).

Incidence in Fish

While the incidence of *C. botulinum* in freshly caught fish in many parts of the world can be very low, in fish from some areas the reported incidence can be very high (Table 41–4). The majority of strains detected formed type E toxin. Notably high incidences were reported in fish from the Swedish Sound (100% of samples), Danish trout ponds (between 5% and 100% of samples), Green Bay in North America (56% of samples), and the Southern Baltic sea (95% of samples). On the basis of tests using PCR, of 647 fish of various types from Finnish fishing waters, 15% were positive for organisms producing type E toxin, with Baltic herring showing an exceptionally high prevalence of 40%.[139]

Several studies have shown a high incidence of *C. botulinum* in fish from fish farms. In trout from one Danish trout farm the MPN counts of *C. botulinum* type E were between 340 and 5,300 spores kg^{-1}.[151] This contamination has been associated particularly with farms that were ground-based with earth bottoms.[151] Several measures were shown to contribute to a reduction of this contamination,[152] and in farms with a concrete base[31,35] or that were sea-based with net bottoms,[5] the reported incidence of the organism was much lower. After catching, gutting fish by hand or machine gave a marked reduction in the incidence of *C. botulinum.*[152]

Many surveys for the presence of *C. botulinum* in prepared fish have shown a very low incidence, but in some cases a high incidence and relatively high numbers have been detected (Table 41–5).[72,127] For example, in salted carp from the Caspian Sea *C. botulinum* type E was detected in 63% of samples at an MPN of up to 490 spores kg^{-1}.[267] In dressed rockfish purchased from a wholesaler in California less than 24 hours after landing of fishing boats, all of seven lots were reported to contain *C. botulinum* type A spores at levels of between 90 and 2,400 spores kg^{-1} and one lot also contained 90 type E spores kg^{-1}.[177] Between 30 and 400 spores of *C. botulinum* type A kg^{-1} were detected in a composite muscle tissue homogenate from eight fresh, gutted, dressed king salmon that originated from Alaska, were kept for 3 to 4 days in ice, and were purchased from a wholesale store, and between 5 and 200 spores kg^{-1} were found in a composite sample from nine fresh, migrating salmon caught at a hatchery in California.[98]

Incidence in Meat

There have been relatively few surveys of the incidence of *C. botulinum* in meat (Table 41–6).

In North America, the reported incidence of *C. botulinum* in meat has been relatively low; in an extensive survey, the ratio of nonbotulinal putrefactive anaerobic sporeformers to mesophilic, proteolytic *C. botulinum* spores was estimated as about 20,000 to 1.[114] In two surveys in the UK, *C. botulinum* was not detected in 280 samples of raw pork,[264] but in three further surveys *C. botulinum* was detected in between 2% and 14% of samples in numbers up to 5 spores kg^{-1}; the highest numbers and incidence were associated with a high proportion of type C strains.

In a study of vacuum-packed bacon produced in experimental cures in a commercial curing cellar in the UK, *C. botulinum* types A and B were detected in 4% to 5% of samples from two lots of pigs and type A was detected in 73% of samples from a different lot of pigs[263] (Table 41–6). This appears to be the highest incidence reported in meat products. In these UK surveys, the conditions used for detection would have favored Group I, proteolytic *C. botulinum* as enrichment was at 35° C and the cultures were not trypsinized.

Incidence in Vegetables and Fruits

In a survey in California in the early 1920s, *C. botulinum* types A or B were detected in 15% of 189 samples of fruit and vegetables (Table 41–7).[203] A further survey across the US resulted in the detection of these types in 13% of 431 samples.[204] In several surveys, *C. botulinum* has not been detected in fruit and vegetables, but in some investigations a high incidence has been found. In a survey of modified-atmosphere-packaged vegetables, one package each of shredded cabbage, chopped green pepper, and Italian salad mix were positive for type A and a further salad mix contained type A and type B spores.[176] The survey focused on Group I proteolytic *C. botulinum,* but as these products are intended for refrigerated storage, it is also relevant to consider the incidence of nonproteolytic *C. botulinum,* particularly type B. The high proportion of outbreaks of botulism associated with the consumption of vegetable foods in some countries indicates the potential for the presence of the organism in these foods.

Incidence in Dairy Products

There have been few studies of the incidence of *C. botulinum* in dairy products; only 12 reported outbreaks of botulism between 1912 and 1989 were associated with dairy products, the majority with cheese or cheese spreads,[55] and two further outbreaks were reported in 1996 and 1997.[17,252] The or-

ganism was not detected in any of 40 samples of Edam and Cheddar or 10 samples of cheese spreads.[156] Unpublished studies at the University of Guelph indicated that the number of *C. botulinum* spores in milk was fewer than one per liter.[55]

Incidence in Honey

Following the original recognition of infant botulism in California, a possible correlation was noted between infant botulism cases and feeding of honey. Extensive testing in the US (Table 41–8) showed that some honey samples contained as many as 10^4 spores of *C. botulinum* kg^{-1}.

In few other countries has testing of honey samples been as extensive as that in the US, but the detection of *C. botulinum* in 6.7% of samples of Sicilian honey and in a relatively high percentage of samples tested in Japan shows that the problem occurs more widely than in the US, and *C. botulinum* type B was found in home-canned honey associated with infant botulism caused by a proteolytic, type B strain in Italy.[88] In some of the tests shown in Table 41–8, samples were heated at 80° C before culture; thus spores of Group II bacteria may have been inactivated, but in many cases tests were also made on unheated honey.

Samples of a brand of honey from Argentina that contained up to 6×10^4 spores of *C. botulinum* type F kg^{-1} also contained high numbers of *Bacillus* spp., in particular *B. alvei*.[217] This bacterium is common in bees affected by European foulbrood; it is suspected to cause opportunistic infection in bee larvae, the true cause of European foulbrood being *Melissococcus pluton*, whereas *B. larvae* causes American foulbrood.[218] *B. alvei* enhanced the growth of *C. botulinum* types A and F in dead bees and bee pupae, and it was suggested that contamination of honey with spores of *C. botulinum* results from multiplication of the bacterium in dead bees facilitated by the depletion of oxygen by *Bacillus* spp.[218]

In a survey in the US of other infant foods for *C. botulinum*, 1.3% of 1001 samples of corn syrup contained about 2 *C. botulinum* spores kg^{-1}.[166] Samples of cereals, formula feed, dried milk, whole milk, commercially canned fruit juice, sugar, and fresh cooked carrots were negative. *Clostridium botulinum* spores were not detected in 43 samples of syrups in Canada but were found in 1 of 40 samples of dried cereal;[136] however, these foods were considered to pose a much lower risk than honey.

C. botulinum was detected in 5.4% of samples of sugar for apiculture, 9.1% of samples of raw sugar, 2

out of 5 samples of molasses, 2 out of 41 samples of brown lump sugar, 1 out of 8 samples of soft sugar (yellow type), and 1 out of 16 samples of corn syrup in Japan, but not from 27 samples of refined white sugar or 25 other sugar products.[220]

Because of the risk of occurrence of *C. botulinum* spores in honey, warnings have been issued in several countries, including the US, UK, and Italy, not to feed honey to infants less than 1 year old. In the US the Food and Drug Administration (FDA) has advised against the use of honey and corn syrup for feeding infants,[166] and in the UK in 1996, the British Honey Importers and Packers Association advised their members to issue new honey labels with the advice that honey "should not be given to infants under 12 months."[33,190]

Incidence in Other Foods

A few studies have been made of the incidence of *C. botulinum* in a range of prepared foods, particularly vacuum-packed products. In tests of 113 samples, type B was detected in 1 sample of luncheon meat and type E in 1 sample of unshucked oysters.[316] Of 100 samples each of boil-in-the-bag foods, vacuum-packed foods, pressurized foods, and dehydrated and freeze-dried foods, only one sample of vacuum-packed frankfurters was found positive for *C. botulinum*, and it contained type B.[156] In tests for the presence of Group II, nonproteolytic strains in refrigerated, packaged foods on sale in the UK, more than 500 samples were tested including raw trout and mackerel; smoked trout and mackerel; ready meals containing chicken and lasagna; salads containing carrots, lettuce, mixed salad, or watercress; and cooked potatoes either filled or plain.[102] Each sample was mixed with a cooked meat medium (CMM) containing glucose and incubated at 10° C, for three weeks before testing for toxin; none of the samples was positive. Following inoculation of packs of food with approximately 2×10^4 spores of nonproteolytic types B and E, after storage for one week at 10° C, toxin was detected in packs of whole trout but not in smoked trout fillets, lasagna, carrots, or baking potatoes with vegetarian cheese. In these last products either inhibitors, such as an acidic pH, may have prevented growth of *C. botulinum* or the concentration of oxygen and the oxidation-reduction potential in packs may have been too high to allow growth under suboptimal conditions. Except in the case of the whole trout, therefore, the experiments did not allow conclusions to be drawn about the incidence of *C. botulinum* spores in packs, but they indicated that the risk of growth and toxin formation in packs of this type within three weeks at 10° C was very low.

The small proportion of food surveyed gives very limited information about the prevalence of *C. botulinum*. It gives an indication, however, that in some circumstances the bacterium may be present in a high proportion of samples of certain types of food and may give some indication of the factors that lead to the presence of the organism. To ensure the production of safe foods, it must be assumed that *C. botulinum* may be present, but a quantitative assessment of the probable incidence of the organism in foods from a wide range of environments is extremely difficult.

41.6 EPIDEMIOLOGY OF FOODBORNE BOTULISM

In such a severe illness as botulism, it would be expected that the proportion of cases actually reported would be higher than in less severe forms of foodborne disease; nevertheless, cases may be unrecognized or misdiagnosed. Botulism has been misdiagnosed until after death as Guillain-Barré syndrome, chemical poisoning, stroke, or staphylococcal food poisoning.[129] In the US between 1983 and 1996, the main form of botulism reported was infant botulism; in 1996 the number of reported cases of infant botulism (82) was almost four times that of cases of foodborne botulism (22) (Figure 41–2).

The relatively high reported incidence of infant botulism in the US, compared with that in other countries, is probably due in part to awareness of the disease by physicians. The number of cases of wound botulism in the US has increased in recent years and is associated with drug abuse, particularly with the injection of heroin; in 1996 the number of reported cases of wound botulism (17) was only slightly lower than that of foodborne botulism (22).[195]

Reported outbreaks and cases of foodborne botulism in countries that show a relatively high incidence of the disease are shown in Table 41–9, together with the foods and toxin types involved. It should be noted that systems of reporting botulism and criteria for reporting outbreaks and cases differ in different countries.[326] Up until the mid-1980s, the reported incidence was particularly high in Poland and China.

The majority of reported outbreaks of foodborne botulism have been caused by organisms forming type A, B, or E toxin. The first outbreak associated with type F toxin was in the Danish island of Langeland in 1958; four people were affected and the outbreak was attributed to the consumption of home-prepared liver paste contaminated with proteolytic *C. botulinum*.[213] The second occurred in 1966 in California and was due to home-prepared venison jerky contaminated with nonproteolytic *C. botulinum*; of 20 people who ate the jerky, 3 developed botulism, 2 suffered mild gastroenteritis, and 15 remained asymptomatic.[207] Three further incidents were referred to by Hauschild in 1993;[129] type F toxin was the suspected cause of an outbreak in Norway in 1970, type F in combination with type A was detected in an outbreak in Argentina in 1981, and in 1986 type F was associated with a further incident in California.

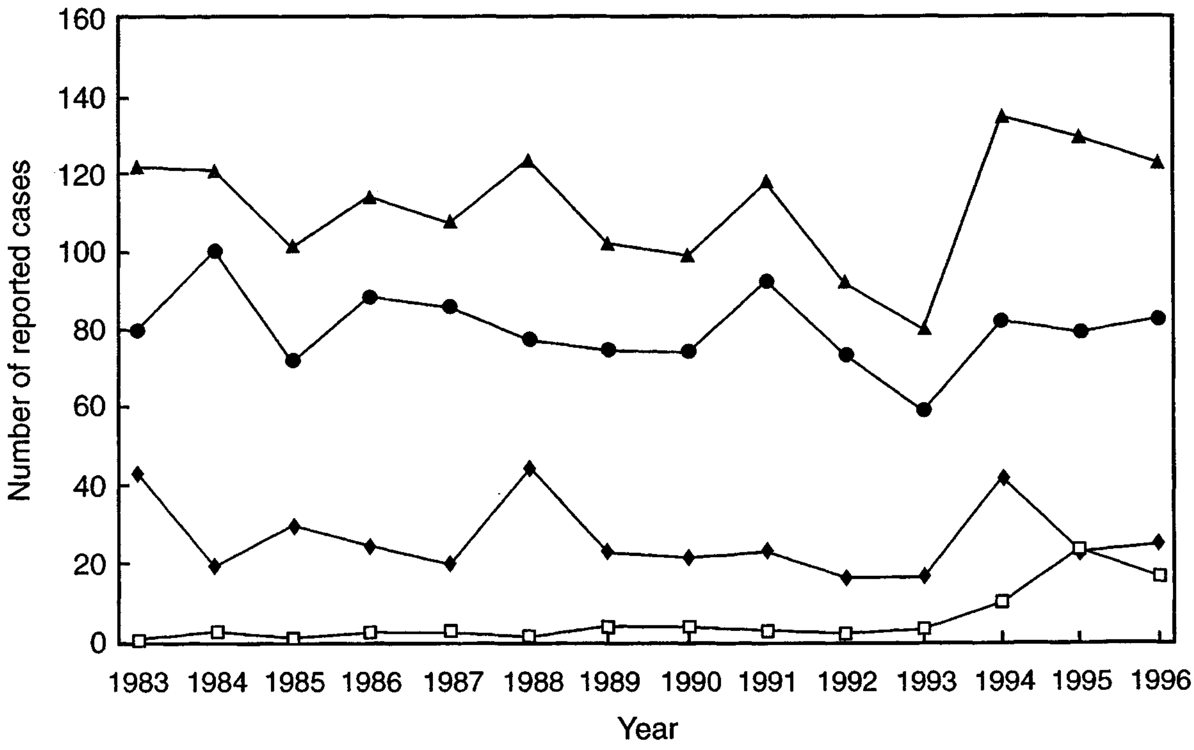

Figure 41–2 Reported Cases of Botulism in the US from 1983 to 1996. ▲, total number of cases; ●, infant botulism; ◆, foodborne botulism; □, wound botulism. Data from reference 195.

A comparison of the number of reported cases of foodborne botulism between 1970 and 1996 in the US, France, Spain, and the UK is shown in Figure 41–3. The number of cases recorded annually in the US has been usually between 10 and 30. In some years a higher number has been reported, several times as a result of restaurant-associated outbreaks. These include an outbreak in 1977 in Michigan, which involved 59 cases and was associated with underprocessing of canned peppers; in 1978 in New Mexico that affected 34 people and was associated with potato salad and/or bean salad; in 1983 in Illinois involving 28 people and associated with temperature abuse of sauteed onions;[129] and in 1994 in Texas that was attributed to consumption of skordalia (a potato-based dip) or meligianoslata (an eggplant-based dip) and affected 30 people.[8] Botulism in France is associated often with consumption of salted, raw hams. Outbreaks of botulism in Spain are attributed generally to consumption of canned vegetables, with asparagus often implicated.[105] In 1987 there was a particularly high reported incidence of botulism in Spain with 11 outbreaks, 46 cases, and 1 death. The foods responsible were determined in six of the outbreaks; five of these were due to home-canned vegetables, the sixth was due to a cured ham.[9] The incidence of foodborne botulism in the UK is low, with a single outbreak reported in each of the years 1978, 1987, and 1989, but the outbreak in 1989 was the largest reported in the UK, affecting 29 people, and was caused by the consumption of a commercially prepared hazelnut yogurt.[233]

Detailed information from countries worldwide was reviewed by Hauschild.[129] The aim of the present discussion is to highlight some of the factors that have led to these cases. The types of food associated with botulism in different countries reflect the methods of food preparation used in those countries (Table 41–9).

Botulism associated with home-preserved vegetables and fruits has resulted (1) when the heat treatment given has been insufficient to inactivate spores of the organism, (2) when growth and acid production by lactic acid bacteria during fermentation has been too slow to prevent germination of *C. botulinum* spores, multiplication of the bacterium, and formation of toxin, or (3) when vegetables pretreated by various means have been covered with oil. The association of botulism with fish products has resulted frequently from insufficient heat treatment

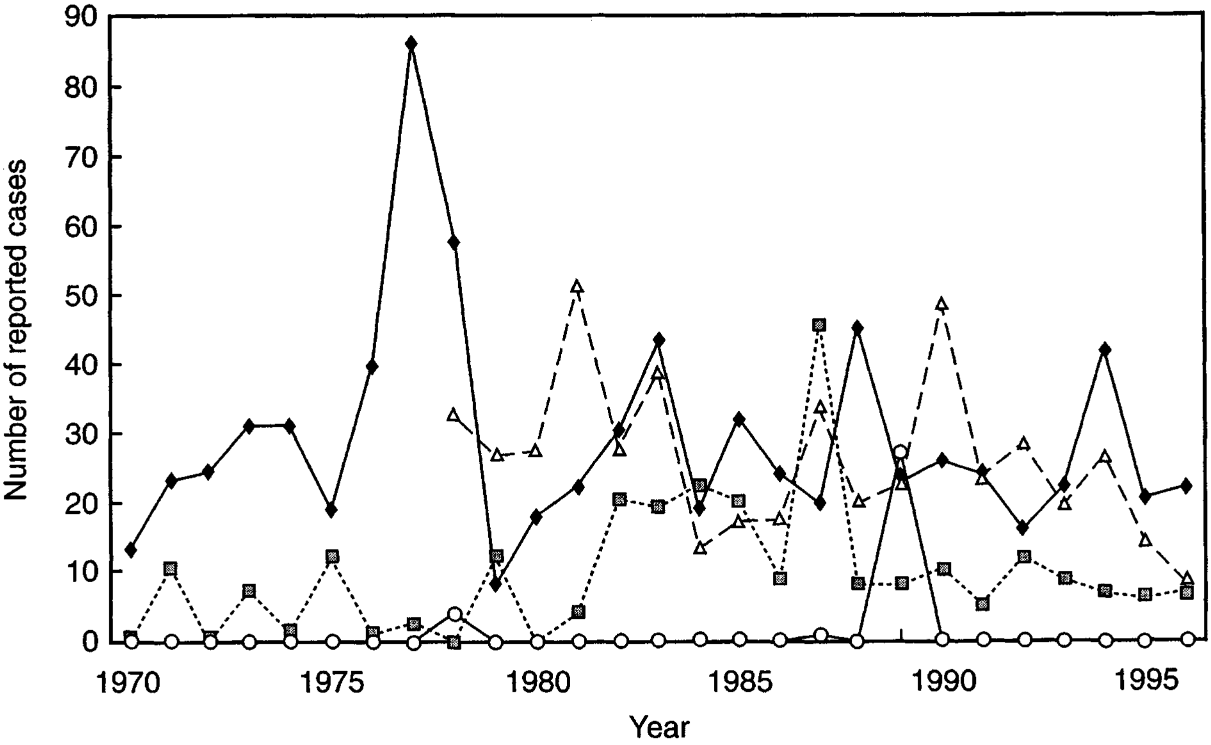

Figure 41–3 Reported Cases of Foodborne Botulism in the US, France, Spain, and the UK from 1970 to 1996. ◆, US; ○, UK; ■, Spain; △, France. Data from references[3,43,64,65,90,191,192,193,195,223,255,334]

or from failure of conditions during fermentation to prevent growth of the organism. In the case of meat products home-preserved by a combination of smoking and addition of sodium chloride (NaCl), botulism has resulted from the failure to achieve a sufficiently high concentration of NaCl to prevent growth of the bacterium.

In Canada, the northern Danish territories, and in many European countries meat products have been the major cause of botulism. A high incidence of botulism was reported from Poland between 1984 and 1987 and was probably due in part to the economic and agricultural situation during this period, which necessitated the home preservation of meats.[179] Between 1984 and 1987, in 830 of 1,791 of the reported cases in Poland, the type of *C. botulinum* involved was determined and 94% of these cases were attributed to type B toxin. The most hazardous practice, which accounted for 60% to 70% of the cases, was reported to be cooking pork in glass jars and storing it under inadequate refrigeration. A relatively large number of outbreaks have been reported from France and Germany, with a high proportion of the cases involving meat products. During World War II, a high proportion of outbreaks in France were due to home- or farm-salted raw hams. The difficult conditions under which pigs were raised and slaughtered, absence of cooling facilities, and shortage of salt contributed to the problem,[179,327] and the high incidence of outbreaks indicates the widespread nature of the bacterium and the potential extent of the problem. In the former West Germany, the number of botulism cases was reported to have declined steadily between about 1960 and 1990, in parallel with a decrease in home canning and curing of foods, particularly meat products.[179] The majority of cases were due to toxic raw hams.

A high proportion of outbreaks in Europe have been due to type B toxin. It has been considered that *C. botulinum* type B strains isolated in Europe were mainly nonproteolytic.[129] Isolates of *C. botulinum* associated with botulism caused by the consumption of raw hams in Central Europe were reported to be nonproteolytic type B strains,[178] but in the case of many of the European outbreaks the causative organisms have not been isolated and characterized. Spores of nonproteolytic *C. botulinum* have generally been considered to have a low heat resistance with a $D_{82.2^\circ C}$ in phosphate buffer pH 7.0 of 0.5 to 2.4 minutes (Section 41.7.3) and on this basis would not be expected to survive the heat processing of the products implicated in the Polish outbreaks. To control foodborne botulism in Europe, there is clearly a need to isolate and characterize bacteria implicated in outbreaks and to determine whether they are Group 1, proteolytic, or Group II nonproteolytic *C. botulinum.*

Fish products have been the major reported cause of botulism in Alaska, Iran, Japan, Norway, Sweden, and the former USSR (Table 41–9).[129] The prevalent isolates in Iran, Japan, and as far as is known in Sweden, produced type E toxin, whereas in Norway strains producing types B and E toxin were each responsible for 47% of cases and one outbreak was associated with type F toxin. Information from the former USSR is limited by the fact that epidemiological work on botulism has been discontinued,[129] but in fish-associated outbreaks between 1958 and 1964, type A toxin was involved in as many outbreaks as type E. The incidence of botulism in native populations of Alaska and parts of northern Canada, in particular in Eskimos and Inuits, is relatively high and is associated with the consumption of fish and marine or land mammals prepared by a process often described as "fermentation" but which, in fact, is usually a putrefaction.[336] Foods such as fish or whalemeat are stored, either raw or partially cooked, often for long periods during which putrefaction occurs because the carbohydrate content of these foods is too low to allow fermentation and sufficient decrease in pH to prevent growth and toxin formation by *C. botulinum.* The major fish products implicated in Iran were salt-cured carp eggs (ashbal); in Japan, fish fermented together with cooked rice, diced vegetables, salt, vinegar, and spices (izushi); and in Norway, raw, fermented trout.

Vegetables have been the major cause of botulism in Argentina, China, Spain, Italy, and the US. With the exception of China, in many of the outbreaks the products were home-preserved by heat treatment, while some outbreaks in Italy have been caused by preservation of vegetables under oil. In China, with a relatively high incidence of botulism, 90% of the reported cases were in the province of Xinjiang (Sinkiang); in outbreaks where the causative food was determined, this was fermented bean curd in 74% of outbreaks and a thick fermented bean sauce in 12% of outbreaks. The predominant causative organisms in Argentina, China, and the US produced type A toxin, whereas in Italy and Spain, type B toxin was involved.

As a result of research over several decades, the controls necessary to prevent the growth of *C. botulinum* in the majority of types of food are well understood. Despite this fact, outbreaks of botulism continue to occur in developed and developing countries. In developed countries, these outbreaks usually are due to failure to understand and apply the known methods of preventing growth of the organism. The majority of outbreaks are attributable to mishandling by home processors or by small-scale processors, but some involve large-scale producers, in which case the consequences of an outbreak can be devastating.

Examples of recent outbreaks that illustrate the continuing problems are shown in Table 41–10.

An outbreak in Taiwan in 1986 was associated with jars of unsalted peanuts in water (ie, a low-acid food) that had been processed by boiling and steaming and was positive for type A botulinum toxin at a dilution of 1:10,000. The producing company was a family-owned business, not licensed to produce canned foods and without a retort device or other steam-pressurized equipment legally required for thermal processing of foods. A recall of the product showed that of 104 jars from the batch implicated, 34 were positive for type A toxin. The authors of the paper stated,

> If other outbreaks of botulism resulted from this or other companies they were either not recognised or not reported. In the current outbreak, about three weeks elapsed from the time of onset of illness among workers in the printing factory until botulism was considered and the public health authorities informed. Clinicians who attended the initial cases assumed the illness was due to chemical exposure in the workplace.

The authors comment that their information suggested that local physicians largely were unaware of the existence of botulism in Taiwan, but that after the publicity resulting from this outbreak, two outbreaks of foodborne botulism associated with home-preserved meats were reported within 4 months and two other sporadic cases were reported.[51] In view of this lack of awareness and underreporting, it is clear that the importance of botulism in Taiwan could not be assessed at least until after 1986.

Following the outbreak in the US and Israel in 1987 due to kapchunka (uneviscerated, salted whitefish), a regulation was introduced to prohibit the processing, distribution, or sale of raw, uneviscerated, salt-cured fish products in New York City.[45,322]

Foodborne botulism in the UK is very rare, but the largest recorded outbreak there occurred in 1989 (Table 41–10) and was caused by the consumption of hazelnut yogurt.[233] Canned hazelnut conserve, an ingredient of the product, was routinely given a mild heat treatment during the canning process, but the

[a] Bp, type B toxin produced by a proteolytic strain of *C. botulinum*

[b] B, type B toxin, not reported whether from a proteolytic or nonproteolytic strain of *C. botulinum*

[c] type E toxin produced by a strain of *C. butyricum*. In all other examples, type E toxin was produced by strains of *C. botulinum*

conserve contained a high concentration of sucrose, which would have prevented growth of *C. botulinum* if it had been present. When batches of conserve were prepared in which sucrose was replaced with aspartame, the heat treatment was not increased and growth of *C. botulinum* was no longer inhibited. Growth of the organism occurred in the canned product before it was added to the yogurt. The yogurt was too acid to allow further growth of the organism, but the amount of toxin in the added hazelnut conserve was sufficient to cause a severe outbreak of botulism.

The outbreak in Cairo, Egypt, in 1991 is the largest reported outbreak due to type E toxin and was caused by consumption of a traditional food (faseikh) prepared by salting uneviscerated mullet fish.[340] The fish traditionally were gathered from the Red Sea or from salt-water lakes, but more recently had been obtained from fish farms. They were stored for between several hours and one day to allow swelling and putrefaction before salting and storing them for between 2 weeks and 1 year. As mentioned in Section 41.5.3, fish farming can allow a build-up of *C. botulinum* in sediments and in the fish, and when salt was added during preparation of the faseikh some time would elapse before the salt penetrated through the fish to give a sufficient concentration to prevent growth of *C. botulinum*.

In Italy in 1995 an elderly woman died from botulism suspected to have been due to the consumption of commercially produced, macrobiotic, canned, low-acid food; the heat treatment during processing was at a temperature no higher than 100° C, and was inadequate to inactivate spores of proteolytic, Group I *C. botulinum*.[97] Of 30 samples from the same production lot that were on the market, 10 samples were positive for botulinum toxin (four for BoNT/B and six for both BoNT/A and BoNT/B); a further three samples that were negative for toxin contained spores of *C. botulinum*. Six of the toxigenic strains isolated produced BoNT/B and seven produced both BoNT/A and BoNT/B; none of the isolates produced BoNT/A only.

41.7 FACTORS AFFECTING SURVIVAL, GROWTH, AND TOXIN FORMATION, PARTICULARLY IN FOODS

41.7.1 Differences between Group I Proteolytic and Group II Nonproteolytic *C. botulinum*

The differences between the physiological properties of proteolytic and nonproteolytic *C. botulinum*, outlined in Section 41.2.1, result in different responses to environmental conditions, in cultures and in foods, and to treatments designed to preserve foods (Table 41–11). During growth in foods, proteolytic strains produce off-odors that tend to reduce the risk that the toxic food will be eaten; nonproteolytic strains do not form off-odors to the same extent and toxin is more likely to be formed in the absence of obvious spoilage.

41.7.2 Oxygen and Redox Potential

Spores of *C. botulinum* survive for long periods in air and can germinate in the presence of oxygen. Growth of vegetative cells, however, can be prevented by the presence of oxygen, which increases the redox potential of a food or medium. The complexity of the relationship between oxygen and redox potential is outlined in Chapter 11. In many cases, inhibition of anaerobic bacteria at high redox potential is probably due primarily to the presence of dissolved oxygen rather than to the redox potential itself; several experiments have shown that high redox potential caused by oxidizing agents other than oxygen may not be inhibitory. For example, growth of a butanol-forming clostridium in a culture medium was inhibited by the presence of sufficient oxygen to raise the E_h to +300 mV at pH 7, but in the absence of oxygen the organism grew at an E_h of up to +335 mV when this was caused by the presence of potassium ferricyanide.[170] *Clostridium acetobutylicum* grew at E_h +370 mV at pH 7 when this was maintained by ferricyanide in the absence of oxygen, but was inhibited at E_h +100 mV when this was produced, in the absence of ferricyanide, by aeration, and was inhibited at –50 mV when this was maintained by dithiothreitol in the presence of oxygen.[227]

In mixed cultures or in foods, other microorganisms and/or enzymes can remove oxygen and create reducing conditions that allow growth of clostridia, or foods may be in packs in which oxygen is lowered, in some cases to extremely low levels. The concentration of oxygen in foods may be highly variable and difficult to control or predict; some foods are highly reducing and, in many types of food, it is unwise to rely for safety on the maintenance of a sufficiently high concentration of oxygen to prevent growth of *C. botulinum*.

In experiments to evaluate the effect of other factors on survival and growth of *C. botulinum*, it is essential that conditions for growth should be highly anaerobic so that the results are not influenced by variable, unknown concentrations of oxygen.[180] This

Table 41–11 Factors Affecting Growth and Survival of Group I, Proteolytic and Group II, Nonproteolytic *C. botulinum*

	Group I, Proteolytic C. botulinum	*Group II, Nonproteolytic C. botulinum*
Minimum temperature for growth	10–12° C	3.0° C
Minimum pH for growth	4.6	5.0
Minimum water activity for growth		
(i) NaCl as humectant	0.96	0.97
(ii) glycerol as humectant	0.93	0.94
NaCl concentration preventing growth	10%	5%
Heat resistance of spores in 0.1M phosphate buffer, pH 7	$D_{121° C}$ maximum 0.21 min	$D_{82.2° C}$ in general up to 2.4 min[a]
Radiation resistance of spores at –50° to –10° C[b]	*D* = 2.0–4.5 kGy	*D* = 1.0–2.0 kGy
Toxins formed	A, B, F	B, E, F

[a] Recovery of spores in the absence of lysozyme (in presence of lysozyme, $D_{82.2° C}$ = 231 min)

[b] The preferred temperatures for food irradiation[168]

is illustrated by experiments comparing the probability of growth from spores of *C. botulinum* type E (strain Beluga) at an E_h adjusted to between +62 and +122 mV by the inclusion of a very small quantity of air, and in highly anaerobic conditions at E_h between –426 and –382 mV (Table 41–12).[183] In the presence of 0.1% NaCl, the probability of growth was 10-fold lower at the high E_h than at the low E_h, ie, at the higher E_h growth would be expected from a moderate inoculum, but increased concentrations of NaCl reduced the probability of growth by much greater factors at the high E_h than at the low E_h.

41.7.3 Heat Treatment

Group I, Proteolytic C. botulinum

Early studies of the heat-resistance of bacterial spores were made in the 1920s to develop processes for the production of safe canned foods, following outbreaks of botulism due to inadequately heat-treated products. Experiments involved determination of the thermal death time (TDT) of spores, defined as "the length of time at different temperatures necessary to destroy a definite concentration of spores in a medium of known hydrogen ion concentration.[24] Investigations by Esty and Meyer[84] with 1,804 concentrated spore suspensions of 109 strains of *C. botulinum* suspended in phosphate buffer at pH 7.0 showed that heat treatments at 100° C for 330 minutes, 105° C for 100 minutes, 110° C for 33 minutes, 115° C for 10 minutes, or 120° C for 4 minutes were necessary to prevent growth at 37° C from 6 × 10^{10} spores of three of the most heat-resistant strains. These workers also showed that at 100° C the log number of spores decreased in a roughly linear manner with time over about 10 log cycles and that a very long delay could occur before germination of heated spores. In juices from some canned foods, the heat-resistance of spores was shown to be greater than that in phosphate buffer. Many further experiments were made to determine TDT curves (see Chapter 3) for spores of proteolytic *C. botulinum* and *C. sporogenes* in phosphate buffer and in foods. The use of phosphate buffer (M/15 Na_2HPO_4 and M/15 KH_2PO_4 mixed to give pH 7.0) as a standard heating medium allows comparison of suspensions of spores on a common basis. The concepts of *F* value and *z* value were introduced, where F_0 = the number of minutes required to destroy the organism (in any specified medium) at 250° F (121.1° C) and *z* = the slope of the TDT curve expressed in °F (or later in °C) (ie, the interval in temperature required for the

Table 41–12 The Combined Effect of Redox Potential, Adjusted with Air or by Exclusion of Air and Addition of Reducing Agents, and NaCl on Log Probability of Growth (Log P) from Single Spores of *C. botulinum* Type E at pH 6.8–7.0 and 20° C in 5 Days[183]

	Log P of Growth at the Indicated Redox Potential	
NaCl (%w/w)	E_h –426 to –382 mV	E_h +62 to +122 mV
0.1	0	–1.0
2.5	–	–2.7

line to pass through one log cycle on semi-log paper). Recalculation by Townsend, Esty, and Basalt[331] of the data of Esty and Meyer showed that for the most heat-resistant spores of *C. botulinum* in phosphate buffer $F_0 = 2.45$ minutes and $z = 17.6°$ F (9.8° C).

The decimal reduction time (*D*-value) is defined as the time required for a 10-fold reduction in viable numbers of organisms at a specified temperature. The *D*-value for *C. botulinum* has been determined by two methods:[308] (1) from graphs of log survivors against time and (2) by an assumption of a logarithmic order of death and calculation of a *D*-value from an initial number and a number surviving after a given heating time at each temperature studied (TDT or end-point method). On the basis of many experiments, particularly by the latter method, for spores of proteolytic *C. botulinum* in phosphate buffer pH 7.0, a $D_{121°C}$ of 0.20 minutes and a z value of 10° C (18° F) are used as a measure of the maximum heat resistance and an F_0 value of 3 minutes at 121° C (or a heat treatment of equivalent lethality at other temperatures) has been accepted as a heat treatment that would reduce the number of viable spores of proteolytic *C. botulinum* by a factor of 10^{12} (a 12-*D* process); this has been adopted as the minimum standard for a "botulinum cook" for low-acid foods[308] (see Chapter 3). Several authors (eg, Anderson et al.,[7] Casolari[41]) have questioned whether an $F_0 3$ treatment gives a 12-*D* process for spores of *C. botulinum*. The fact remains that use of this concept has led to the safe production of canned, low-acid foods for many decades, and the majority of cases of botulism due to low-acid canned foods have been due to failure to deliver this process. In practice much greater heat treatments are needed very often to minimize spoilage, because of the presence of spores with greater heat-resistance than those of proteolytic *C. botulinum*. While the number of heat-treated spores that result in growth is affected greatly by components of a culture medium or food, the estimated number of surviving spores of proteolytic *C. botulinum* is not greatly increased by the presence of hen egg-white lysozyme during recovery[6,248,280] in contrast to spores of nonproteolytic *C. botulinum*.

Group II, Nonproteolytic C. botulinum

Spores of these bacteria are much less heat-resistant than those of proteolytic *C. botulinum*. The heat-resistance of spores of nonproteolytic *C. botulinum* is important in relation to foods that are preserved by a combination of mild heat treatment and storage under refrigeration (Section 41.9). Reported *D*-values, determined by TDT methods and by enumeration of survivors, are shown in Table 41–13. The highest *D* values at 82.2° C in phosphate buffer pH 7.0 have generally been in the range of 0.4 to 2.4 minutes.

In fact these heat treatments result in sublethal injury of the spores by inactivation of the germination system.[182,238,241] Lysozyme can enable germination of these injured spores and the addition of lysozyme to the medium used to enumerate survivors results in a marked increase in the number of colonies formed and gives a biphasic survivor curve (Figure 41–4).[6,130,240,281,289] This biphasic curve resulted because lysozyme can diffuse through the coat of only a proportion of the heat-damaged spores (for most strains 0.1% to 1%), but treatment of the heated spores with sodium thioglycollate disrupted the coat of the majority of the sublethally damaged spores; this allowed the ingress of lysozyme and resulted in germination and colony formation, giving a straight line graph of the log number of survivors against time and providing evidence of the mode of action of lysozyme (Figure 41–4).[241] The *D*-values for lysozyme-permeable spores heated in phosphate buffer and recovered in the presence of lysozyme were much greater than those obtained when the spores were recovered in the absence of lysozyme (Table 41–13). Lysozymes from many sources and other enzymes with lysozyme activity, when included in the recovery medium, can increase the number of surviving spores that give colonies after heat treatment.[238,306] Lysozyme activity has been detected in many raw foods, often at a level higher than that required to increase the measured heat-resistance of spores of nonproteolytic *C. botulinum*, and lysozymes can be relatively heat-stable;[182,239] this is potentially important in foods that rely for safety on heat-inactivation of spores of nonproteolytic *C. botulinum*. Studies in which five replicate containers of a model food (meat slurry) per treatment, with no added lysozyme, were each inoculated with 10^6 spores of a mixture of eight strains of nonproteolytic *C. botulinum* showed that while heat treatments at 85° C for 36 minutes or 90° C for 10 minutes were sufficient to prevent growth and toxin formation during subsequent incubation at 25° C for 60 days,[91] when hen egg-white lysozyme (2400 units ml^{-1}) was added to this model food prior to heating, after heat treatments at 85° C for 84 minutes or 90° C for 34 minutes growth was observed at 25° C after 13 and 14 days respectively.[92] In similar experiments a total of 50 containers of meat slurry containing lysozyme (625 units ml^{-1}) each inocu-

[a] Counts—plate counts; TDT—Thermal death time or end-point method

[b] Egg yolk emulsion included in the plating medium

[c] Hen egg white lysozyme included in the plating medium at 625 units ml^{-1} (10 $\mu g\ ml^{-1}$)

lated with 10^6 spores of a mixture of 8 to 12 strains of nonproteolytic *C. botulinum* were heated at 95° C for 15 minutes; growth and toxin formation occurred in seven of the containers after subsequent incubation at 25° C for less than 60 days.[243] A similarly high heat-resistance has been reported for spores of nonproteolytic *C. botulinum* in crab meat. Experiments in which 30 packs of Dungeness crab meat per treatment were each inoculated with 10^6 spores of a mixture of three strains of nonproteolytic *C. botulinum* type B showed that process times of 50 to 60 minutes at 88.9° C or 90.6° C, 30 to 40 minutes at 92.2° C, or 7 to 17 min at 94.4° C were required to prevent the survival of spores, determined by enrichment at 27° C for up to 150 days.[247] Enzymes with lysozyme activity have been reported in fresh crab at a concentration of about 200 $\mu g\ g^{-1}$.[182] Even when the effect of lysozyme is taken into account, however, at 95° C spores of nonproteolytic *C. botulinum* are of the order of 20-fold more heat-sensitive than those of proteolytic *C. botulinum*. A $D_{95^\circ C}$ value of 4.4 minutes was reported for lysozyme-permeable spores of nonproteolytic *C. botulinum* strain 17B in the presence of lysozyme.[242] In similar tests, spores of 8 strains of proteolytic *C. botulinum* gave $D_{95^\circ C}$ values of 35–92 minutes[244] while extrapolation from a $D_{121^\circ C}$ of 0.2 minutes with $z = 10^\circ C$ would give a $D_{95^\circ C}$ of 80 minutes.

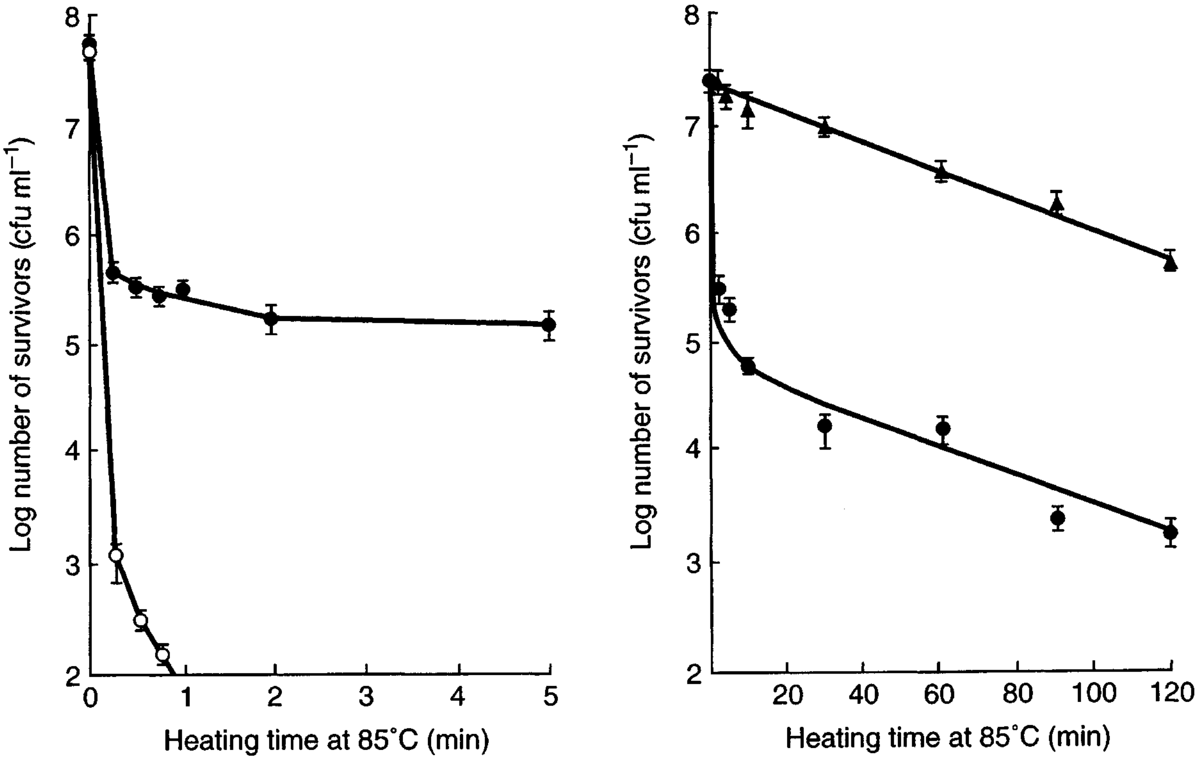

Figure 41–4 The Number of Spores of Nonproteolytic *C. botulinum* Strain 17B That Survived Heating at 85° C in Phosphate Buffer pH7, Estimated by Plating on Medium without Lysozyme (O—O), with Lysozyme, 625 Units (10 µg) per ml (●—●) and after Treatment with Alkaline Thioglycollate before Plating on Medium Containing Lysozyme (▲—▲) and Incubation at 30° C.[240,241] Bars represent 95% confidence limits.

41.7.4 Irradiation

The effect of irradiation on spores of *C. botulinum* has been investigated extensively since the 1960s. With the advice of the World Health Organization that from the point of view of public health there is no upper limit to the dose that can be used,[349] the prospect of using irradiation not only as part of a combination treatment but as a single means of effecting a 12-*D* kill of *C. botulinum* spores becomes theoretically possible. In order to minimize sensory changes in foods, irradiation is done preferably at a temperature in the range of −50° to −10° C.

Survival curves for irradiated spores tend to be log linear against time, often with an initial shoulder.[127] *D*-values for spores of proteolytic *C. botulinum* at −50° to −10° C in neutral buffers and in foods are in the range of 2.0 to 4.5 kGy, while spores of nonproteolytic type E have *D*-values in the range of 1 to 2 kGy.[168] In the temperature range of −200° C to +50° C, *D*-values decrease by approximately 0.01 kGy per °C rise in temperature.

As in the case of heat-treated spores, germination and growth from spores that survive irradiation are influenced by components of the surrounding medium. In addition, growth from irradiated spores is improved markedly by the inclusion of magnesium ions in the culture medium; this may be due in part to the fact that a ligase involved in repair of DNA is dependent on magnesium ions.[168]

41.7.5 Storage Temperature

Group I, Proteolytic C. botulinum

The minimum temperature for growth and toxin production is between 10° and 12° C. Growth and toxin formation at 12° C in 3 to 4 weeks[248,288] and doubling times of 84 to 93 hours at 12.5° C have been reported.[230] Generally no growth has been detected at 10° C or below;[230,248,288] although Tanner and Oglesby[321] reported growth at 10° C from a vegetative inoculum, the work was marred by a temporary rise in the temperature of the incubator to 20° C, and in the words of the authors "the results of this test may not be very significant." These authors did not observe growth at 10° C from a spore inoculum in 10 weeks. In experiments in which 10 g or 20 g quantities of food were mixed with 50 ml of spore suspension containing approximately 6 x 10^8 spores of proteolytic *C. botulinum* and incubated at 10° C, toxin was detected occasionally, and inconsistently, after 4 days or 14 days.[320] This appears to be the only published report of detection of toxin after incubation of food containing proteolytic *C. botulinum* at 10° C. These results may have been due to the release of pre-formed toxin from within the spores, rather than growth and *de novo* synthesis of toxin.[113]

Group II, Nonproteolytic C. botulinum

The minimum temperature at which growth and toxin production have been reported is 3.0° C;[112] in this study, inoculation of 10^5 spores into 10 ml of medium resulted in growth at 3.0° C after 7 weeks. Growth and toxin production had been previously reported at 3.3° C within 31 to 39 days.[79,80,276] Growth and toxin formation have not been detected during incubation at 2.1 to 2.5° C for 90 days.[79,80,112,231,276] Doubling times of a type E strain at 5°, 10°, and 20° C were reported as 42.6 hours, 7.2 hours, and 1.9 hours respectively,[231] whereas for the type B strain 17B doubling times at 5°, 10°, and 20° C were 28.6 hours, 5.7 hours, and 1.9 hours respectively.[109] The fact that there is a risk of growth from small numbers of spores of nonproteolytic *C. botulinum* in foods stored under refrigeration is illustrated in Table 41–14.

41.7.6 pH and Acidulants

The majority of evidence indicates that in otherwise optimal conditions the minimum pH for growth from spores of proteolytic *C. botulinum* is between pH 4.6 and 4.8. Occasional reports of growth and toxin production in high protein media at pH 4.1 to 4.4[290,317,346,354] may be due to the presence of a microenvironment at higher pH. In experiments using vegetative bacteria as inoculum (to avoid any effect of pH on germination, which might be highly variable between spore crops), in a strictly anaerobic medium, adjustment of the pH to 4.6 with hydrochloric acid (HCl) reduced the probability of growth from individual cells of a type A strain at 30° C by a factor of $10^{5.6}$ compared with that at pH 6.8 (ie, provided a safety factor of approximately 6*D*).[185] In the majority of foods, acidity is due to the presence of organic acids such as acetic, lactic, and citric acids, in which case the undissociated acid, or possibly a chelating effect in the case of citric acid,[108] will provide an additional inhibitory effect at an acid pH. Growth and toxin formation by nonproteolytic *C. botulinum* have not been detected at a pH lower than 5.0.[18,111,127] Despite the fact that at 20° C and below growth was prevented at pH 4.5 to 5.1 in the presence of citric acid, spores of proteolytic and nonproteolytic *C. botulinum* survived for 56 days with no significant decrease in numbers.[186]

41.7.7 NaCl and Water Activity

Growth of proteolytic *C. botulinum* is prevented by 10% (w/w) NaCl, giving a water activity of about 0.93. Two strains were able to grow in a culture medium at water activity (a_w) 0.96 but not at a_w 0.95 with NaCl as humectant, and at a_w 0.93 but not at a_w 0.92 with glycerol as humectant.[18]

Nonproteolytic strains of *C. botulinum* do not grow at an NaCl concentration above 5% w/w.[18,111] In strictly anaerobic conditions (E_h7 between –426 and –382 mV), 4.0% (w/v) NaCl reduced the probability of growth at 20° C from spores of the Beluga strain of type E by a factor of about $10^{4.2}$.[183] Growth from spores of the Beluga strain was initiated at a_w 0.97 but not at a_w 0.96 with NaCl as humectant; growth from vegetative cell inocula occurred at a_w 0.98 but not at a_w 0.97 with NaCl as humectant and at 0.95 but not at a_w 0.94 with glycerol as humectant.[18]

41.7.8 Nitrite

This has been used for many years to inhibit *C. botulinum*, primarily proteolytic strains, in cured meat products and in fish products [see Chapter 9; and Section 41.9]. Many studies have been made to evaluate its effect and, because of the concern about nitrosamines, to investigate alternative inhibitors. The effect of nitrite on growth of *C. botulinum* in meat products is influenced considerably by the pH and by components of the product such as available iron and ascorbate or isoascorbate; this fact can limit the value of studies of the effect of nitrite on *C. botulinum* in culture media and in model foods. Nevertheless, such studies have provided useful information on the mechanism of inhibition.

The effect of heat treatment on proteolytic *C. botulinum* is much greater apparently in the presence than in the absence of curing salts (mainly NaCl, 2.5% to 4.0% and $NaNO_2$, up to about 200 mg kg^{-1}). This effect is due mainly not to an increased destruction of spores but to inhibition of growth

Table 41–14 Examples of Reported Time to Toxin Formation in Foods Inoculated with a Low Concentration of Spores of Nonproteolytic *C. botulinum*

		Time (Days) to Toxin Formation at Specified Temperature							
Food	*Inoculum (spores g^{-1})*	*4° C*	*5° C*	*8° C*	*10° C*	*12° C*	*16° C*	*25–30° C*	*Reference*
Turkey	10^2	–[a]	–	8	–	5	2	1	201
Cod	5×10^1	18	–	8	–	6	–	1	250
Salmon	10^2	21	–	6	–	3	–	1	99
Catfish	10^2	46	–	6	–	–	3	–	256
Red snapper	10^2	NT[b]	–	9	–	3	3	1	20; 177
Red snapper	10^3	21	–	9	–	3	3	1	20; 177
Cooked cauliflower	10^3	–	19	17	13	–	4	2	38; 39
Cooked mushroom	10^3	–	20	10	10	–	3	1	38; 39

[a] Tests not carried out at this temperature

[b] No detectable toxin formed in 60 days

from the heated spores by the curing salts.[154] During heat processing and storage of meat products, the concentration of nitrite decreases due to interaction with other components. For nitrite to contribute to inhibition of *C. botulinum*, the starting concentration must be sufficiently high that the residual nitrite level is inhibitory. There is evidence that inhibition of *C. botulinum* by nitrite at concentrations used in cured meats is due to an inactivation by nitric oxide of iron-sulphur proteins such as ferredoxin and pyruvate oxidoreductase within the germinated cells.[329]

41.7.9 Sorbic Acid

Group I strains of *C. botulinum* have been reported as relatively resistant to sorbic acid, which can be used as a carbon source by these bacteria.[352,353] The use of media containing 1,200 mg sorbic acid kg^{-1} was suggested for selective enrichment of *Clostridium* spp. including *C. botulinum*. The only Group II strain tested was less resistant to sorbic acid than Group I strains and did not use a significant quantity of the acid. Despite these reports, there is evidence that potassium sorbate at a concentration up to 2,600 mg kg^{-1} (2,000 mg sorbic acid kg^{-1}) could be used to replace a high proportion of the nitrite added to cured meat products as an inhibitor of *C. botulinum*[296,344] and that addition of potassium sorbate to poultry products,[118,147] ham and bacon,[148] and cheese spread[29] delayed growth and toxin formation by this bacterium.

The maximum concentration of sorbic acid permitted in many foods in the UK and Europe is 1,000 mg kg^{-1} or mg l^{-1}, and in some foods, including processed cheese, is 2,000 mg kg^{-1}.[86,303] In the US, the maximum permitted level of added sorbates as sorbic acid is between 1,000 and 2,000 mg kg^{-1} with some exceptions (eg, in regular cheese the maximum level must not exceed 3,000 mg kg^{-1}).[294,295] A sorbic acid concentration of 2,000 mg l^{-1} had little or no effect on growth of vegetative *C. botulinum* type A strain ZK3 at a pH of 6.0 to 7.0 and 30° C but at pH 5.5, 1,828 mg total sorbic acid l^{-1}, equivalent to 281 mg undissociated sorbic acid l^{-1}, reduced the probability of growth in 14 days by more than 5 logs compared with that at pH 5.5 in the absence of sorbic acid.[184] Similar results were obtained with four further type A strains and five proteolytic type B strains. After growth had occurred, the majority of the sorbic acid was degraded. Germination of spores of proteolytic *C. botulinum* at 35° C and pH 6.5 was inhibited by 12,839 mg sorbic acid l^{-1} (equivalent to 229 mg undissociated sorbic acid l^{-1}), at pH 5.7 by 3,881 mg sorbic l^{-1} (equivalent to 229 mg undissociated sorbic acid l^{-1}) and at pH 5.5 by 1,941 mg sorbic acid l^{-1} (equivalent to 298 mg undissociated sorbic acid l^{-1}).[25,293]

The effect of sorbic acid on growth of nonproteolytic *C. botulinum* has received less attention than that on proteolytic strains. At 20° C and pH 5.5, 1,796 mg sorbic acid l^{-1} (equivalent to 276 mg undissociated sorbic acid l^{-1}) reduced the probability of growth in 60 days from single vegetative cells of nonproteolytic type B strains by >3 logs while 1,300 mg sorbic acid l^{-1} (equivalent to 200 mg undissociated sorbic acid l^{-1}) reduced the probability of growth by only approximately 1 log,[187] whereas at 12° C and pH 5.5, 974 to 1,300 mg sorbic acid l^{-1} (equivalent to 150 to 200 mg undissociated sorbic acid l^{-1}) reduced the probability of growth by about 5 logs.

At pH 5.5 or lower, sorbic acid at concentrations commonly used in foods can provide a considerable safety factor preventing growth of *C. botulinum*, provided that the fat content of the food is not sufficient to take up a high proportion of the undissociated acid; in combination with other factors such as refrigeration, this safety factor can be increased.

41.7.10 Other Antibacterials

Other additives that can contribute to inhibition of *C. botulinum* in foods include nisin, which is used in pasteurized cheese spreads, esters of parahydroxybenzoic acid, phenolic antioxidants, polyphosphates,[168] and CO_2; in addition, ascorbates and certain chelating agents enhance the inhibitory effect of nitrite.

41.7.11 Combinations of Preservative Factors

Preservative factors at a level that singly do not give a high safety factor against the growth of *C. botulinum* can be combined to give a high level of protection; the safety of many foods relies on such combinations of preservative factors (Section 41.9). For example, in the absence of a heat treatment the combined effect of pH, adjusted with HCl, and water activity adjusted with NaCl on growth from spores of single strains of type A, proteolytic type B, and type E is shown in Table 41–15. On the basis of studies of the effect of combinations of factors in culture media and in foods, predictive models have been developed of the combined effect of factors such as temperature, pH, and NaCl on growth of proteolytic *C. botulinum*.[19,246,341] In relation to foods that do not receive a heat treatment, the combined effect of pH (adjusted with HCl) and NaCl on time to growth of nonproteolytic *C. botulinum* at chilled temperatures has been investigated (Figure 41–5).[112] Several predictive models have been developed that describe the effect of controlling factors on growth of nonproteolytic *C. botulinum*.[238]

Because of the interest in foods preserved by a mild heat treatment in combination with refrigeration and other preservative factors, several studies have been done of the combined effect of heat treatment and preservative factors on growth from spores of nonproteolytic *C. botulinum*. A model was developed of the combined effect of heat treatment at 70° to 90° C and storage temperature at 5° to 25° C on growth from 10^6 spores of a mixture of strains of nonproteolytic *C. botulinum* in otherwise optimal conditions.[91] In these experiments, in which lysozyme was not added, heat treatments at 70° C for 2,545 minutes, 75° C for 464 minutes, 80° C for 70 minutes, 85° C for 23 minutes, and 90° C for 10 minutes each prevented growth at 8° C for at least 42 days. Experiments in which lysozyme 2,400 units ml^{-1} (50 $\mu g\ ml^{-1}$) was added to the medium before heat treatment showed that a greater number of spores were able to germinate and give growth after heat treatments at 85° C and 90° C than in the absence of added lysozyme, and a predictive model was developed describing the combined effects of heat treatment at 70° to 90° C followed by storage at 5° to 25° C on the time to growth with lysozyme present before heating.[92] The combined effects of heat treatment, pH, NaCl concentration, lysozyme addition, and storage temperature on time to growth from 10^6 spores in a model food system have also been described.[110,245]

41.7.12 Factors Affecting the Stability of Neurotoxins in Foods

The primary concern in preventing foodborne botulism is to control food production so that formation of BoNTs is prevented. Detailed information is available on thermal inactivation of these toxins in foods.[285] In general, the rate of inactivation is reported not to be linear, the toxins are most heat-stable at about pH 5.0, and food components can protect the toxins against heat-inactivation. Studies of BoNT/A, BoNT/B, BoNT/E, and BoNT/F in several types of food indicate that a concentration of 10^5 mouse $LD_{50}\ g^{-1}$ was reduced to < 1 $MLD_{50}\ g^{-1}$ by heating at 85° C for 5 minutes or less. BoNTs reportedly are more resistant to irradiation than are spores of Group I *C. botulinum*. Frozen storage at –15°C or lower in several types of food has little or no effect on the activity of BoNTs (in the complexes in which they usually occur in foods), but in some foods the heat-resistance of BoNT/E decreased after frozen storage.[285]

41.8 PRINCIPLES OF DETECTION AND ISOLATION

41.8.1 Cultural Methods for Isolation

Isolation may be required for studies of the incidence of *C. botulinum* in the environment or in foods, for detection of the organisms in foods suspected of being implicated in outbreaks of botulism, or from clinical samples from patients and for investigation of the properties of isolates. The various types of samples present different problems of isola-

tion. Some of the difficulties in isolation of *C. botulinum* were referred to in Section 41.5.1. As proteolytic *C. botulinum* and nonproteolytic *C. botulinum* are physiologically distinct, different conditions are required for their isolation. Heat treatment of samples is used frequently to eliminate competing vegetative bacteria, heating at 75° to 80° C for 10 to 15 minutes is useful in culturing from spores of proteolytic *C. botulinum*. A lower temperature, eg, 60° C is used sometimes during isolation of nonproteolytic strains, and the addition of lysozyme to the enrichment medium can increase the recovery of the heated spores [Section 41.7.3].[282] Unheated samples should be cultured also to isolate vegetative bacteria or spores that are not fully heat-resistant. Treatment with ethanol is used as an alter-

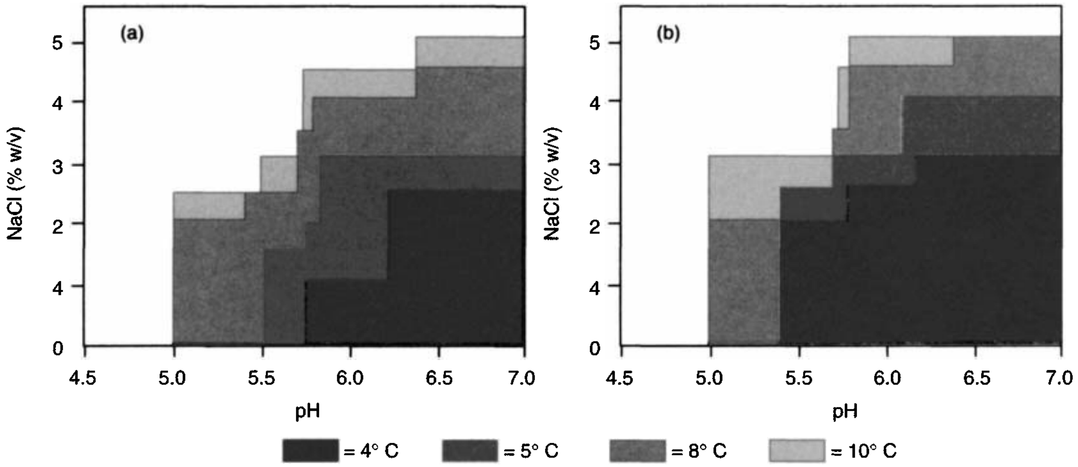

Figure 41–5 Combinations of pH (Adjusted with HCl) and NaCl That Prevented Growth and Toxin Production from Spores of Nonproteolytic *C. botulinum* Types B, E, and F at 4°, 5°, 8°, and 10° C within 3 Weeks (Figure 41–5a) and 6 Weeks (Figure 41–5b). Vials containing 10 ml of PYGS medium were inoculated at 10^4 spores ml^{-1} and incubated at the designated temperature. Intervals of 0.5% NaCl and approx. 0.4 pH units were used. Growth was observed visually and the presence of toxin was confirmed using the mouse test. After 3 weeks, growth was observed at 4° C in vials containing 0.5% NaCl but not in vials containing 0.1% NaCl. *Source:* Data from A.F. Graham, D.R. Mason, F.J. Maxwell and M.W. Peck. Effect of pH and NaCl on growth from spores of non-proteolytic *Clostridium botulinum* at chill temperatures, *Letters in Applied Microbiology*, Vol. 24, pp. 95–100 © 1997, Blackwell Science Ltd.

native to heat treatment for isolation of spores of nonproteolytic *C. botulinum*.[299] Media for enrichment must be anaerobic.[123,167,282,299] In media that are not too highly colored, the redox dye resazurin (which is reduced to the colored resorufin, which is then reversibly reduced to colorless dihydroresorufin, $E'_m = -51$ mV) can be used as an indicator of adequate deoxygenation of the medium[183] (see Chapter 11). To enrich for proteolytic *C. botulinum*, samples should be inoculated into CMM and incubated at 35° C, whereas for nonproteolytic *C. botulinum* CMM glucose medium, chopped meat glucose starch medium[127] or trypticase-peptone-glucose-yeast extract broth containing trypsin (TPGYT) can be used with incubation at 26° C.[299] Trypsin is included to inactivate bacteriocins (boticins) that may be produced by closely related clostridia. Cultures should be incubated for 7 days, or longer if necessary, to allow growth, sporulation, and toxin formation. After enrichment, a portion of the culture can be used to test for BoNT and a further portion plated onto a suitable solid medium. Before plating, the sample of enrichment culture may be treated by heating (in isolation of proteolytic organisms) or with ethanol in order to eliminate competing vegetative bacteria.[299] A suitable nonselective solid medium is egg-yolk agar on which colonies of *C. botulinum* groups I and II have a typical appearance associated with their lipase activity. Several selective plating media have been used including *C. botulinum* Isolation (CBI) agar[69] and Botulinum Selective Medium (BSM);[210] these are useful for detection of proteolytic, Group I *C. botulinum* but the trimethoprin in these media inhibits nonproteolytic Group II strains. Colonies suspected to be *C. botulinum* are characterized by toxin formation and their physiological characteristics.[123,292]

41.8.2 Detection of Neurotoxins by Injection into Mice

Intraperitoneal injection into mice has been the standard method for detection and identification of BoNT,[123] the procedure, controls necessary, and the interpretation are described by Solomon et al.[299] To detect toxin formed by Group II, nonproteolytic *C. botulinum* treatment of samples with trypsin is necessary to convert the single chain toxin to the more toxic dichain form. A collaborative study showed that this method was repeatable and reproducible for the detection of toxin produced by proteolytic and nonproteolytic *C. botulinum* in foods.[164] The specificity of the test is achieved by the use of specific antisera and by observations of typical symptoms of botulism in the mice prior to death. Assays for quantitative determination of BoNT have been developed, and a stable reference standard preparation of BoNT/A was prepared, enabling the response of laboratory mice under a given set of conditions to be assessed and the toxin content of an unknown sample to be expressed in terms of the equivalent of ng BoNT/A g^{-1} or ml^{-1}.[272] Intraperitoneal injection will detect as little as 5 to 10 pg of type A toxin and provides a measure of the biological activity of the toxin.[123] Alternative methods involving a range of animals have been described;[237] these include subcutaneous injection into mice resulting in flaccid paralysis of muscles rather than death, which is as sensitive as intraperitoneal injection but may be less convenient. Advantages of these biological tests are their extreme sensitivity and their ability to detect previously undescribed BoNTs, atypical toxins, and antigenic variants. Disadvantages are the undesirability of using animals and the need to wait several days before a sample can be judged negative.

41.8.3 Detection and Assay of Neurotoxins by ELISA and Other Immunological Techniques

Immunological methods for the detection of BoNTs include enzyme-linked immunosorbent assays (ELISAs) and other tests.[237] Some of the ELISAs have the same sensitivity and specificity as the mouse test and are cheap and easy to use. The ELISA tests have the following limitations:

- some may react with biologically inactive toxin
- some may react differently with toxins of a specific type produced by different strains, since these toxins may differ in antigenicity[74,82,103,104,150]
- some of the tests use antibodies that were raised to preparations containing a mixture of antigens, so that the tests are not specific for BoNTs[150,251,269]
- many ELISAs need a complex and expensive amplification system to achieve the sensitivity of the mouse test.[74,212,284]

Despite these limitations, ELISAs have been used widely. For example, within 2 hours of sample receipt, an ELISA was used to demonstrate the presence of type B toxin in samples of hazelnut purée and yogurt associated with the outbreak of botulism in the UK in 1989.[261] Accounts of at least 20 different ELISAs have been published, some of which are described in Table 41–16.

Immunological techniques have been used also to identify colonies of proteolytic *C. botulinum* types

Table 41–16 Examples of Some of the More Sensitive ELISAs Developed for Detection of *C. botulinum* Neurotoxins

Toxin Type	*Used with Foods*	*Minimum Detection Limit (MLD_{50} ml^{-1})*	*Comments*	*Reference*
A	yes	5–10	No cross reaction with other clostridia, denatured toxin, or other toxin types, but failed to detect toxin produced by one type A strain. Complex amplification system used.	103, 284
B	yes	20	No cross reaction with other clostridia or other toxins, but failed to detect toxin produced by one type B strain. Complex amplification system used.	104, 212
F	yes	10	No cross reaction with other clostridia or toxins of types A, B, or C. Very slight cross reaction with type D toxin; slight reaction with type E toxin.	93
A, B	yes	1–32, <1–16	ELISA may respond to antigens with no neurotoxicity. Correlation between the response from ELISA and mouse bioassay not consistent.	150
A, B, E	yes	9, <1, <1	Cross reaction with some other clostridia. Used extensively to measure toxin production by proteolytic and nonproteolytic *C. botulinum* in meat and in vegetable preparations. Also reacted with strains producing type F toxin.	38, 91, 251
A, B, E	yes	1, 1, 1	Weak reaction with toxin from some strains, suggesting the presence of biologically inactive, but immunochemically reactive, neurotoxin. Used to measure toxin production by nonproteolytic *C. botulinum* in fish fillets. Complex amplification system used (ELCA-ELISA).	74, 75, 266
A	no	1–2	Developed for therapeutic preparations.	82
E	yes	1–10	No cross reaction with other toxins or other clostridia.	347

A and B[106] and nonproteolytic *C. botulinum* type E.[70,106]

41.8.4 Detection and Assay of Neurotoxins by Endopeptidase Activity

Two types of highly specific *in vitro* assay for BoNTs have been developed that are based on their endopeptidase activities. In HPLC-based methods, after incubation of the BoNTs with their substrate (SNAP–25 or VAMP), the substrate and breakdown products are separated by HPLC and assayed by their absorbance.[83,278,342] The HPLC methods are less sensitive than the mouse test and are not suited to rapid detection of toxin in large numbers of samples.

Methods using a combination of endopeptidase activity and immunological reaction have been developed for measurement of BoNT/A and BoNT/B.[81,119] The advantages of these methods over previous ELISA procedures include: (1) they measure the biological activity of the light chain of the toxin (but not of the heavy chain); (2) variations in antigenicity of toxins of a specific type do not influence the response; and (3) the problem resulting from antibodies having been raised to a mixture of antigens is eliminated. In these tests, a fragment of the target protein (SNAP–25 for toxin of type A, VAMP for type B toxin) is attached to a microtiter plate and serves as the substrate. The sample containing neurotoxin is added and, after a period of incubation, specific antibodies are added that bind to the cleaved target protein, followed by secondary antibodies and detection system. Endopeptidase assays have been developed for BoNT/A and BoNT/B that were specific and did not cross react with other BoNTs;[119] the mean detection limits were 260 MLD_{50} ml^{-1} for BoNT/A and 380 MLD_{50} ml^{-1} for BoNT/B. Sensitivity was increased approximately 10-fold by an amplification system. An endopeptidase assay developed for therapeutic preparations of BoNT/A correlated well with the mouse assay and was more sensitive, with a detection limit of 0.2 to 1.0 MLD_{50} ml^{-1}.[81] A combination of endopeptidase and ELISA has many advantages, but further development is required before it can replace the mouse test. Possible problems include interference by other proteases and positive reaction with toxin that is inactive *in vivo*, because the endopeptidase assays relate to the biological activity of the light chain and would not be affected by inactivation of the biological activity of the heavy chain. Assays are being developed that capture the toxin on an immunoaffinity column prior to an endopeptidase assay; these assays show considerable promise in foods and will probably become commercially available.

41.8.5 Use of PCR and Gene Probes To Detect Neurotoxin Genes

Probes have been constructed that enable PCR tests for the nonspecific detection of genes for all types of BoNT[34] and for the specific detection of genes for each of the toxins.[87,94,96,315] Following a cultural enrichment, these methods correlated well with tests for toxin using mice and, with the inclusion of an MPN series of dilutions in the cultural enrichment, have been used for quantitative detection of *C. botulinum* type E inoculated into fish (enabling detection of 210 spores kg^{-1}) and for investigation of the presence of bacteria containing these genes in aquatic sediments and in fish.[11,138,139] The use of a cultural enrichment provides a relatively high number of target bacteria, improves sensitivity, and minimizes possible problems due to the presence of extracellular DNA or to dead bacteria or to interference by food components.

41.8.6 Choice of Method of Detection and Isolation

Cultural enrichments are necessary for isolation and production of pure cultures of organisms that form BoNT and for investigation of their physiological properties. Except in the case of foods in which toxin has been formed, or in some clinical samples, they usually are required prior to tests for toxin.

The use of mice for detection of toxin clearly has been an essential tool in the development of our understanding of *C. botulinum*, in the detection of outbreaks of botulism, and in the understanding of procedures necessary to prevent foodborne botulism. For some time to come, tests in mice may be necessary for reference purposes and for the detection of any neurotoxins of new antigenic types. With the development of the alternative methods described above, however, tests using mice can now be minimized. Increasingly, a great deal of information about the occurrence of these organisms in the environment and in foods can be obtained by cultural enrichment combined with immunological, endopeptidase, or genetic techniques. In studies of factors that affect growth and toxin production by *C. botulinum* in culture media and in foods, which involve tests with known strains, immunological methods can be used very easily for the detection of toxin and, therefore, for confirmation of growth of the organism.[38,91,307] Increasingly, *in vitro* methods can be used to test large numbers of samples for the probable presence of organisms that form BoNT, making possible investigations that in the past have been inhibited by the need for the use of animals.

41.9 CONTROLS TO PREVENT GROWTH OF AND TOXIN FORMATION BY *C. BOTULINUM* IN FOODS

41.9.1 General Principles

Down the centuries, preservation of food has evolved by trial and error until, during the twentieth century, it became possible to evaluate quantitatively the factors that contribute to preservation and safety and to control these factors in order to build in safety. Methods of controlling *C. botulinum* in foods were discussed by Hauschild.[127] The factors that are used to control *C. botulinum* in major categories of food are illustrated by examples summarized in Table 41–17.

The foods that risk being contaminated with the highest levels of *C. botulinum* are probably raw fish from certain sources, and contamination is usually particularly high in the intestine. Evisceration of fish as soon as possible and thorough washing of the fish to reduce the spore load are important steps in reducing the initial level of *C. botulinum.*[76]

41.9.2 Category 1. Shelf-Stable Products, *C. botulinum* Controlled by Heat Processing; Low-Acid Canned Foods

The term low-acid foods is applied in the UK to foods with a pH >4.5[68] and in the US to foods with a pH >4.6.[333] These are considered to be foods with a pH that could allow growth of *C. botulinum*. If canned, these foods must, in general, receive a heat treatment that is sufficient to reduce by a factor of 10^{12} the number of viable spores of proteolytic *C. botulinum* (an $F_0 3$ process). The requirement for thermal destruction of *C. botulinum* in these foods was discussed in Section 41.7.3. In the case of most low-acid, canned foods, heat treatment greater than $F_0 3$ is required to inactivate spores of other species of *Clostridium* and of *Bacillus* with greater heat-resistance than those of *C. botulinum*. While most cases of botulism associated with low-acid canned foods result from underprocessing in the home, some have been caused by commercial products. In recent years, for example, the outbreaks due to heat-processed peanuts, and to hazelnut conserve added to yogurt (Table 41–10), and the case due to a macrobiotic food (Section 41.6) were due to the failure of commercial processors to apply known principles. Following restaurant-associated outbreaks of botulism involving foods heat-processed in-house using faulty techniques, regulations in Canada and in some US states specify that "no in-house (non-commercial) canned or bottled foods may be served in restaurants."[129]

Next Page

Table 41–17 Examples of Main Factors Used To Control *C. botulinum* in Foods

Product Category	*Main Factors Controlling C. botulinum*	*Examples of Foods*
Shelf-Stable Foods		
1	Heat process > $F_0 3$	Low-acid, canned foods, pH > 4.5 (UK) or pH >4.6 (US)
2	Heat process < $F_0 3$, NaCl, nitrite	Shelf-stable, canned cured meats
3	Heat process < $F_0 3$, pH	Canned acid foods pH ≤ 4.5 (UK) or pH ≤ 4.6 (US) eg, many types of canned fruit and vegetables
4	a_w (NaCl + drying) ± nitrite. Refrigeration below 5° C during salting	Raw salted and salt-cured meats, eg, salt pork, salt bacon, salt hams, dry-cured hams, and bacon
5	a_w (NaCl + drying) nitrite, pH	Fermented sausages (eg, summer sausage, pepperoni, acidulated sausages)
Perishable Foods		
6	Refrigeration alone	Raw meat, fish, and vegetables
7	NaCl, refrigeration, nitrite in many products, in some cases sorbate, benzoate, nitrate, or smoke	Salted raw fish, lightly preserved fish, semi-preserved fish, hot-smoked fish, perishable cooked, cured meats
8	a_w (NaCl and other components), pH, refrigeration of some products, mild heat treatment	Process cheese and process cheese spreads
9	Mild heat treatment, refrigeration, limited shelf-life	Ready meals, "sous vide" foods

Food poisoning has been caused by post-processing contamination of canned foods. The majority of incidents of this kind have been caused by *Staphylococcus aureus*, but a few have been caused by *C. botulinum*. An outbreak of botulism in the UK in 1978, which affected four people causing the death of two,[21] resulted from the exposure of cans of salmon to contaminated materials during cooling. Measures to prevent such contamination include careful handling of cans, the use of water of good microbiological quality for cooling cans, well-controlled chlorination of cooling water, and regular cleaning and disinfection of conveyers and equipment used for handling cans.[68,140]

There is evidence that some batches of canned foods in which BoNT has been formed have reached the consumer but have not been reported to have caused botulism.[127] For example, in surveys by the US FDA in 1973 to 1974, 20 production lots of commercially canned mushrooms from nine US and foreign canneries contained BoNT but none of the products was involved in botulism. Reasons contributing to this may be:

1. most canned vegetables and some canned meats are heated before consumption, which may inactivate toxin
2. in underprocessed foods, any surviving strains of *C. botulinum* usually would be proteolytic and would produce unpleasant odors in the food, possibly preventing consumption
3. mild symptoms might not be diagnosed and reported.

In general, growth of clostridia in underprocessed canned foods usually leads to gas formation and swollen cans; in canned fish products where the main type of *C. botulinum* present is likely to be nonproteolytic type E, or if canned foods in general are contaminated with a nonproteolytic strain after heat-processing as occurred in the outbreak due to canned salmon noted above, formation of toxin may occur before the food is sufficiently spoiled to prevent consumption. Because spores of putrefactive, nontoxic anaerobes usually outnumber those of *C. botulinum* (by up to 10^4:1) in the environment, the majority of swollen cans are not toxic.[127]

41.9.3 Category 2. Shelf-Stable Products, C. *botulinum* Controlled by Heat-Processing, Sodium Chloride, and Nitrite; Shelf-Stable, Canned Cured Meats

The main products in this category are luncheon meats and canned cured hams. Additional factors that affect the preservation of these products are the pH and iron content of the meat and additives such as ascorbates, isoascorbates, and polyphosphates.[127,134,179] The heat processing given to such products can be between $F_0 0.01$ and $F_0 1.5$,[134] but is usually in the range of $F_0 0.05$ to 0.6. This results in destruction of vegetative microorganisms but not of spores of Group I *C. botulinum*, and the preservation of these foods relies on the combined effect of the heat treatment and inhibition of growth from surviving spores. The magnitude of the protective effect against *C. botulinum* in these foods can be expressed as:

$$\mathrm{Pr} = \mathrm{Ds} + \mathrm{In}$$

where **Pr** = the protection factor (ie, the number of 10-fold reductions in the probability of growth and toxin production per spore)

Ds = the number of 10-fold reductions in viable spores caused by the heat treatment

In = the number of 10-fold reductions in the probability of growth caused by inhibition.[134]

For shelf-stable, canned cured meats with a brine concentration of 5.0% to 5.5%, a nitrite input level of 150 ppm and heat-processed to F_0 of about 0.6, the protection factor was estimated as between 6 and 10, depending on the heat-resistance of the spores used in the experiments.[126] The tendency has been to reduce the brine content of such products, and reducing the level to 4.0% to 4.5% (as used in 1982) would decrease the protection factor by about 2; complete elimination of nitrite from a product containing 5.0% to 5.5% brine would give a similar reduction. Some manufacturers were reported to have compensated for the reduction in salt by increasing the heat treatment of the product, but this increase was limited by adverse sensory effects on the product. Hauschild[126] concluded that data he presented largely supported the view of the Committee of the US National Academy of Sciences/National Research Council that shelf-stable, canned cured meats were likely to become hazardous to health if nitrite was reduced from an input level of 150 ppm or omitted.

From a consideration of the quantities of shelf-stable, canned cured meats that had been produced and sold commercially and had not caused botulism, protection factors varying from >6 to >8.2 were estimated.[134] On this basis combinations of brine concentration, thermal process, and initial nitrite concentration that contributed to this level of safety were summarized (Table 41–18). It was concluded that lowering any one of these factors would require an increase in one or both of the other factors.

41.9.4 Category 3. Shelf-Stable Products, C. *botulinum* Controlled by Mild Heat Treatment and Acidity; Acid Canned Foods

The term acid foods is applied to foods with a pH ≤4.5 (UK) or ≤4.6 (US). The majority of evidence shows that growth of *C. botulinum* is inhibited at pH 4.6 and below, with the possible exception of very rare and specialized conditions. Acid canned foods are given a heat treatment much less than an $F_0 3$ process, but sufficient to inactivate microorganisms that are able to grow at an acid pH. Some botulism outbreaks have occurred due to acid canned foods. Such outbreaks may be due to three possible causes:

1. inadequate heat treatment may allow survival of acid-tolerant microorganisms that subsequently grow, raise the pH, and thus allow growth of *C. botulinum*
2. post-process contamination with acid-tolerant microorganisms may have the same effect
3. the food (eg, vegetables) may have been acidified insufficiently before canning.[127]

All 35 cases of botulism reported in the US in the period 1928 to 1978 and attributed to "acid foods" involved home canning and were associated with prior growth of another microorganism that raised the pH, permitting growth of proteolytic *C. botulinum*.[302]

41.9.5 Category 4. Shelf-Stable Products, C. *botulinum* Controlled by Reduced Water Activity, Sodium Chloride, Sometimes Also Nitrite, and Refrigeration during Salting; Shelf-Stable Raw Salted and Salt-Cured Meats

Examples of products are salt pork, dry-cured bacon, the dry-cured hams produced in continental Europe, and country-style ham produced in the US.[160,328] In raw cured, shelf-stable meats, the main salts used in curing are NaCl and nitrites, the latter being added partly to improve the color and flavor of the product. The cure may be applied as a dry salt, by injecting the meat, or by a combination of these methods. In com-

Table 41–18 Combinations of Brine Concentration and Thermal Process That, in Conjunction with a Nitrite Input of 150 ppm, Were Estimated To Ensure the Safety of Shelf-Stable, Canned Cured Meats from *C. botulinum*, ie, To Give a Protection Factor[a] of at Least 6.6[134]
[% brine = (NaCl x 100)/(NaCl + H_2O)]

Product	*Brine Concentration %*	F_o
Luncheon meats	3.0–4.0	1.0–1.5
	4.0–4.5	1.0
	4.5–5.0	0.5–1.0
	5.0–5.5	0.5
Ham and shoulder	3.3	0.3–0.5
	3.7	0.2–0.3
	4.0	0.1–0.2
Sausages	2.5	1.5

[a] Protection factor calculated as log number of cans produced none of which were reported to have caused botulism

Source: Reprinted with permission from A.H.W. Hauschild and B. Simonsen, Safety Assessment for Shelf-Stable Canned Cured Meats—An Unconventional Approach, *Food Technology*, Vol. 40, No. 4, pp. 155–158, © 1986, Institute of Food Technologists.

mercial production in Europe, brine (containing 10% to 20% (w/v) NaCl and 0.1% to 0.15% (w/v) nitrite or nitrate)[14] is injected usually into the meat. During the initial curing and ripening, the product should be maintained below 5° C to prevent the growth of nonproteolytic *C. botulinum*, particularly type B.[157] In the case of dry-cured hams, when the a_w in all parts of the ham has fallen below 0.96, the temperature of drying is raised first to <15° C then later to 18° to 20° C. The product is smoked at up to 22° C; the a_w of the final ham is less than 0.90. The combination of high content of salt and nitrite and the low a_w resulting from curing and drying makes these products shelf-stable. In Europe home- or farm-produced, dry-salted hams have been a major cause of botulism due to strains forming type B toxin; this occurred particularly during periods of stress such as World War II.[179,327] Factors contributing to these incidents probably included shortage of salt and failure to maintain the hams below 5° C during the early stages of salting.

41.9.6 Category 5. Shelf-Stable Products, *C. botulinum* Controlled by Reduced Water Activity, Acidity, and Nitrite; Dry Fermented Sausages

These products include summer sausage, pepperoni, and acidulated sausages and are described in Chapter 19. The acidity and drop in pH resulting from growth of starter organisms combined with the low water activity of the final product prevent growth of *C. botulinum*, which does not appear to be a hazard in these foods[127] (see Chapter 19).

41.9.7 Category 6. Perishable Products, *C. botulinum* Controlled Mainly by Refrigeration

Examples of food in this category are red meats, which are transported worldwide in vacuum packages in low-permeability plastic film at temperatures of about 0° C; as a result of respiration of the tissue, high concentrations of CO_2 develop. Clostridia are usually not present in deep tissues of meat. They are likely to be present on the surface but on raw meat they tend to compete poorly with other bacteria and spoilage occurs before growth and toxin production by *C. botulinum.*[179] There are, however, reports of spoilage by psychrotrophic *Clostridium* spp. of refrigerated, vacuum-packed raw meat maintained below 3° C.[27,61,162]

The Inuit population of northern Canada and the Eskimo population of Alaska have a history of eating putrid, raw meat of marine mammals. This practice has led to numerous outbreaks of botulism caused by nonproteolytic *C. botulinum*, which is probably favored by the low temperatures. Consumption of raw, fresh meat has not been reported as the cause of botulism in any other part of the world;[179] the main factors that can be used to control safety are probably minimization of contamination of the meat from the intestinal contents at slaughter, maintenance at low temperature, rejection of meat showing spoilage, and cooking before consumption.

Vacuum- and modified atmosphere-packaging are used extensively for commercial, refrigerated bulk shipment of raw fish. The risk of botulism associated with raw fish is greater than that due to raw meats because of the higher rate of contamination with *C. botulinum* spores, and because the predominant strains present are nonproteolytic and therefore toxin formation can occur before noticeable sensory deterioration. In a study in which 100 spores of *C. botulinum* type E 100 g^{-1} sample were inoculated into fresh salmon, which was then stored at 10° C in air, in 60% CO_2 + 25% O_2 + 15% N_2, or 90% CO_2 + 10% N_2, formation of toxin was delayed in the CO_2 atmospheres; but after 10 days, samples in air were spoiled and toxic whereas samples in the CO_2 atmospheres contained toxin but were not overtly spoiled.[76] Thus inhibition of the spoilage microflora by the CO_2 could increase the shelf-life of the fish but increased the risk due to *C. botulinum*. In a further study of salmon fillets surface-inoculated with 100 spores of type E g^{-1} of fish, toxin was detected before spoilage in packs containing 75% CO_2 + 25% N_2 and stored at 16° C but not in packs under air or vacuum or in packs stored at 4° or 8° C.[257] At 4° C sensory spoilage occurred but toxin could not be detected many days later. Experiments of this kind have given different results, probably due in part to differences in the initial quality of the fish, in the initial number of spoilage organisms, in number and properties of the *C. botulinum* strains present, and in the nature of packs. The results indicate, however, that modified-atmosphere packaging (MAP) can delay spoilage and increase the shelf-life of raw fish but does not reduce the risk of growth of *C. botulinum*, and the safety of such products depends on very strict control of temperature to about 4° C or lower. Practices have been used to preserve fresh fishery products in CO_2 in conditions where the temperature can be controlled (eg, at 2° C); the products are then removed for retailing, allowing growth of spoilage bacteria to resume to ensure that spoilage occurs before the product might become toxic.[76]

Outbreaks of botulism have been associated with unexpected foods in which the safety of the product was dependent on refrigeration but temperature abuse occurred. In North America, two outbreaks of botulism have been attributed to a product containing chopped garlic in soybean oil.[216,305] The first of these outbreaks, due to type B toxin, was one of the largest reported in North America, affecting 36 people, while the second, also due to type B toxin, affected 3 people. The commercially manufactured products were labeled "keep refrigerated" (in small print) but were, in fact, kept at room temperature for a prolonged period. The oil content of these products presumably created sufficiently anaerobic conditions to allow growth of *C. botulinum*. After the second of these outbreaks, the FDA ordered companies to stop production of any garlic-in-oil mixes that are protected only by refrigeration, and such products must now contain specified concentrations of antimicrobial agents or of acidulants such as phosphoric or citric acid.[216]

41.9.8 Category 7. Perishable Products, *C. botulinum* Controlled Mainly by Sodium Chloride and Refrigeration, Often in Combination with Nitrite, Sometimes with Other Factors Such As Sorbate, Benzoate, and Nitrate; Salted Fish, Lightly and Semipreserved Fish Products, Hot-Smoked Fish, Perishable, Cooked Cured Meats

An example of a salted, raw fish product is kapchunka, which is prepared by layering raw, uneviscerated fish and salt; after storage for a minimum of 25 days, the fish are rinsed and air-dried at ambient temperature for 3 to 7 days.[76] After drying, the fish should be marketed under refrigeration and often are eaten uncooked. This type of food has caused several outbreaks of botulism (Table 41–10) probably because growth of *C. botulinum* and production of toxin had occurred before an inhibitory concentration of salt had diffused through the fish. The risks associated with raw, salt-cured fish can be reduced considerably by careful evisceration of the fish to reduce the level of possible contamination with spores of *C. botulinum* from the viscera, by ensuring that a high salt concentration is attained as rapidly as possible throughout the fish, and by keeping it under refrigeration during production, distribution, and sale.[76]

Lightly preserved fish include products such as pickled "gravad" fish. These are a Scandinavian food prepared from fillets of salmon, halibut, or trout that are sprinkled with salt, sugar, and spices and are left to ripen at chill temperature for 1 to 2 days (see Chapter 21). Gravad fish often are prepared in the home, and failure to use an adequate amount of salt or to maintain at low temperature has resulted frequently in cases of botulism. Some types of lightly preserved fish also contain sorbate, benzoate, nitrite, or smoke. In vacuum-packed, cold-smoked trout inoculated with a mixture of spores of nonproteolytic *C. botulinum* types B, E, and F to give 810 cfu kg^{-1} or 20,210 cfu kg^{-1}, a water-phase concentration of 3.4% NaCl failed to prevent toxin formation at 4° or 8° C within 6 weeks; toxin was also formed in trout cured with 3.4% NaCl and 166 mg $NaNO_2$ kg^{-1} but not in samples treated with 3.4% NaCl plus 686 mg KNO_3 kg^{-1}.[153] In a further experiment in which vacuum-packed, cold-smoked trout were inoculated with spores of a mixture of strains of type E to give 140 cfu kg^{-1} or 4,140 cfu kg^{-1} a water-phase concentration of 3.4% NaCl failed to prevent toxin formation at 4° or 8° C in 6 weeks but the presence, in addition, of an initial concentration of 109 mg $NaNO_2$ kg^{-1} or 347 mg KNO_3 kg^{-1} prevented toxin formation.

Semipreserved fish products (eg, salted or marinated herring, anchovies, and caviar) usually contain a higher concentration of NaCl than lightly preserved products; some may also contain sorbate, benzoate, or nitrate. Some types of caviar contain >10% NaCl and are shelf-stable, whereas other types contain <10% NaCl and are stored under refrigeration[131] (see Chapter 21). Hauschild and Hilsheimer[131] concluded in 1978 that most of the commercial types of caviar that they examined contained combinations of pH and salt that would inhibit proteolytic

C. botulinum at ambient temperatures. In Europe, many types of caviar are maintained below 10° C, and control of NaCl and refrigeration are important for the safety of these products (see Chapter 21). There are few reports, all prior to 1980, in which caviar has been associated with outbreaks of botulism.[127]

Hot-smoked fish such as salmon, mackerel, and trout are heated commonly at 60° to 80° C.[76] The heat treatment is not sufficient to inactivate spores of nonproteolytic *C. botulinum,* although they may be damaged. The addition of NaCl is of major importance in the control of *C. botulinum,* and both nitrite and smoke can reduce the concentration of NaCl required. After an evaluation of many experiments, Eklund[76] concluded that 3.5% NaCl in the water phase would be adequate to inhibit growth of *C. botulinum* type E in vacuum-packed, smoked fish that are smoked at least during the first half of the process and heated to an internal temperature ≥63° C for a minimum of 30 min. If 100 to 200 mg $NaNO_2$ kg^{-1} was included in the process, the water-phase concentration of NaCl could be reduced to 3.0%, but in the US, $NaNO_2$ was permitted only in a limited number of types of fish.

Perishable cooked, cured meats include emulsified products such as frankfurters and liver sausage, coarse-ground chopped meats, sectioned and formed meats such as ham, prime cuts, and jellied meats. The heat treatment used during production depends on the products, and internal temperatures required by the US Department of Agriculture vary from 60.0° C to 76.6° C.[160,328] Hauschild[126] considered that "these products are safe from *C. botulinum* as long as they are properly refrigerated" and that the risk to be considered was that resulting from temperature abuse. From challenge experiments by several groups of researchers, the probability of toxin production from spores of proteolytic *C. botulinum* inoculated into wieners, chicken frankfurters, turkey roll, and liver sausage during incubation at 27° C for 1 week was determined. In most cases, the probability of a single spore giving rise to toxin in the product in these conditions was $<1 \times 10^{-4}$, ie, the protection factor was greater than 4, but in turkey roll with 3.2% to 3.4% brine and 0 to 50 mg nitrite kg^{-1}, the protection factor was only about 3. In liver sausage with 3.8% to 4.2% brine but with no nitrite, the probability of growth and toxin production in these conditions was about 3×10^{-4}, equivalent to a protection factor of about 3.2, but the addition of 50 to 150 mg nitrite kg^{-1} with the same concentration of brine reduced the probability of growth and toxin formation to $<2 \times 10^{-6}$ in the presence of 150 mg nitrite kg^{-1}, ie, gave a protection factor of about 6.

41.9.9 Category 8. Perishable or Shelf-Stable Products, *C. botulinum* Controlled by Mild Heat Treatment, Reduced Water Activity, Acidity, and Refrigeration of Some Products; Process Cheese and Process Cheese Spreads

During the production of these spreads, cheese mixed with the other ingredients is heated to between 80° and 98° C before filling into the final containers. In the US, pasteurized, process cheese spreads with a pH generally in the range 5.4 to 6.0 and a moisture content of about 50% are mostly distributed as shelf-stable products in hermetically sealed containers.[301,318] In some other countries, these types of products are intended for refrigerated storage, but they may be subjected to temperature abuse. The heat treatment may be sufficient to give a high level of inactivation of spores of nonproteolytic *C. botulinum* but will not inactivate spores of proteolytic strains, inhibition of which will depend on a combination of pH and water activity, controlled by NaCl and other ingredients, and in some cases by refrigerated storage.

Combinations of pH, NaCl plus disodium phosphate, and moisture that prevented toxin formation in process cheese spreads from an inoculum of spores of type A and B proteolytic strains at 30° C have been determined.[318] In further experiments, in process cheese prepared with a_w 0.95 and pH 5.55 and inoculated with spores of a mixture of type A and B proteolytic strains, no growth occurred within three months at 15° to 30° C.[323] In addition to the effects of a_w and pH, the stability of the products was increased by the presence of lactic acid originating from the cheese and decreased by substitution of some of the phosphate emulsifying salt by citrate. The results of a series of experiments, in which the effect of composition of cheese spreads on growth of proteolytic *C. botulinum* was determined, were used to derive a model predicting the effect of composition on time to toxin production.[324] The addition of nisin inhibited growth of proteolytic *C. botulinum* in process cheese spreads; a nisin concentration of 12.5 ppm was effective in some formulations while 100 to 250 ppm was needed to inhibit *C. botulinum* in cheese spreads with the highest moisture levels or with lowest sodium levels.[301]

An outbreak of botulism in Argentina in 1974 caused by a commercial cheese spread with onions focused attention on the safety of these products.[28] A survey of samples of Argentine commercial cheese spread showed that a_w values varied between 0.968 and 0.978 and pH values were between 5.6 and 6.1. Following inoculation of spores of *C. botulinum* type A into cheese spread with an estimated a_w of 0.970 and pH 5.7, growth and toxin formation occurred after incubation for 30–70 days at 30° C.[28] It was concluded that process cheese spreads could pose a safety hazard if subjected to temperature abuse (ie, at room temperature in tropical areas or during the summer), and that a method of reducing the hazard would be to lower the water activity of the product by the addition of components such as whey powder, NaCl, emulsifying salt (phosphate), and glycerol. The addition of potassium sorbate 0.3% w/w delayed toxin production by *C. botulinum* type A in a model system for cheese spread (apparently lacking in fat) and increased the margin of safety,[29] but in products with a high fat content this effect of sorbate would probably be reduced.

The inclusion of components such as vegetables and herbs in products of this type and any reduction of the concentration of NaCl and increase in the moisture content require an evaluation of the effects on safety with respect to *C. botulinum*.

41.9.10 Category 9. Perishable Products, *C. botulinum* Controlled by Mild Heat Treatment and Refrigeration; Ready Meals, "Sous-Vide" Foods

In northern European countries, there is a trend toward the increased production of precooked foods or meals for catering or for retail sale that are intended to have a shelf-life of up to 3 or 6 weeks at refrigeration temperature.[181,238] The safety of many of these foods with respect to *C. botulinum* depends mainly on a pasteurization heat treatment combined with refrigerated storage and a specified shelf-life and often they do not contain other preservative factors. The terms "Refrigerated, processed foods of extended durability (REPFEDs)" and "New generation refrigerated foods" have been applied to these products, but the former term, particularly, can apply to foods in categories 7 and 8 as well as to category 9 of Table 41–17. In the production of "sous vide" products, the food is packaged in heat-stable, air-impermeable bags under vacuum, the bags are sealed, and the product is cooked (pasteurized), cooled, and stored under refrigeration. In general REPFEDs are prepared by one of the following methods: (1) foods are packaged then cooked, or (2) foods are cooked then packaged, or (3) foods are cooked, packaged, then heated again.

These foods are given a much less severe heat treatment than are shelf-stable canned foods, with the aim of producing foods with a better flavor. The heat treatment, in the temperature range of 65° to 95° C, has little effect on spores of Group I, proteolytic strains of *C. botulinum* but damages or inactivates spores of Group II, nonproteolytic strains. It is essential, therefore, that throughout storage these foods should be maintained at a temperature below 10° C (ie, below a temperature that will allow growth of Group I strains).

In Europe, recommendations have been published that the heat treatments given to these foods or the combination of heat treatment with inhibitory factors should reduce the probability of survival and growth of nonproteolytic *C. botulinum* by a factor of 10^6 (ie, provide a protection factor [Pr] of 6). The UK Advisory Committee on the Microbiological Safety of Foods (ACMSF)[3,4] concluded that the safety of extended shelf-life chilled foods with respect to nonproteolytic *C. botulinum* could be ensured by one of the following:

- storage at <3.3° C
- storage at ≤5° C and a shelf-life of ≤10 d
- storage at 5 to 10° C and a shelf-life of ≤5 d
- a heat treatment at 90° C for 10 min or equivalent lethality followed by storage at <10° C
- a pH of <5.0 throughout the food combined with storage at <10° C
- an NaCl concentration of >3.5% throughout the food combined with storage at <10° C
- a water activity of <0.97 throughout the food combined with storage at <10° C
- other combinations of heat treatment and preservative factors together with storage at <10° C that can be shown consistently to give a protection factor of 6.

Similar guidelines have been issued by the European Chilled Food Federation (ECFF) and other organizations.[85,107,194] A draft code relating to these foods has been produced by the Codex Alimentarius.[53] It should be noted that growth and toxin production have now been reported at 3.0° C.[112]

There are very few circumstances under which it is possible to rely on maintenance of chilled foods at a temperature below 3.0° C for long periods of time (eg, > 5 days).[181] It is clear from surveys that while many firms are able to maintain these low temperatures in the distribution chain, during storage in retail conditions and by consumers such low temperatures cannot be maintained reliably.[258] The current regulations in Europe require chilled foods in general to be maintained at 0 to 3° C in Spain, 0 to 4° C in France, ≤7° C in Belgium, and ≤8° C in the UK.[238]

Many extended shelf-life chilled foods have a pH higher than 5.0, an NaCl content lower than 3.5%, and a water activity higher than 0.97. Thus the major factors that can be used to ensure the safety of these foods are the combination of heat treatment and maintenance of a storage temperature below 10° C, together with a specified shelf life. In foods that are packaged after the heat treatment, strict control of hygiene is necessary to prevent recontamination with pathogenic or spoilage bacteria.

Pasteurized, canned meat from the blue crab (*Callinectes sapidus*) has been produced in the US for many years. The standard practice, published in 1970, was reported in 1992 to involve heating cans of crab meat in a water bath at 88° C until cold-point temperatures reached 85° C for 1 minute. This process has been calculated to give an average heat treatment equivalent to 31 minutes at 85° C, assuming a z value of 8.9° C.[260] In conjunction with good manufacturing practices, experience in the industry indicated that this heat treatment gave a shelf-life for the product of 6 to 18 months, a storage temperature of 2.2° C or below being stipulated in the standards endorsed by the national Blue Crab Industry in the US.[260] The results described in Section 41.7.3 indicate that, unless blue crab meat causes an increase in the heat-sensitivity of spores of nonproteolytic *C. botulinum*, the heat treatment usually given to canned blue crab meat may give only a low level of inactivation of spores of nonproteolytic *C. botulinum*, many spores being sublethally damaged. This would mean that storage at a temperature ≤2.2° C is an integral factor required to ensure safety with respect to *C. botulinum*. Failure to maintain this low storage temperature could entail a risk that the sublethally damaged spores would germinate and result in growth and formation of toxin.

Tests to determine whether the pasteurization process for the blue crab could be applied to meat of the Dungeness crab (*Cancer magister*) showed that the heat process was inadequate to destroy 10^4 spores of *C. botulinum* type E and that toxin could be formed before the product showed signs of spoilage; thus the product would not be safe under conditions of temperature mishandling.[175] On the basis of end-point experiments, a process time of 50 to 56 minutes at 90.6° C or 7 to 17 minutes at 94.4° C was necessary to inactivate 10^6 spores of a mixture of three strains of nonproteolytic *C. botulinum* type B.[247] These processes are more rigorous heat treatments than the 90° C for 10 minutes proposed by the ACMSF and the ECFF for REPFEDs. As an extra precaution, the authors recommended storage of pasteurized Dungeness crab meat below 38° F (3.3° C).[247]

A series of publications has demonstrated combinations of heat treatment, pH, NaCl, storage temperature, and time that prevent growth and toxin formation from 10^6 spores of *C. botulinum* in a model food (meat slurry) (ie, that provide a protection factor of 6) and predictive models have been developed.[91,92,110,239,243] This work has shown, for example, that in a model food with added lysozyme, after heat treatment equivalent to 90° C for 34 minutes or 95° C for 15 minutes followed by storage at 25° C, growth occurred after 14 days and 32 days respectively; this indicates a heat resistance of a similar order to that reported in the Dungeness crab meat.[247] If, however, storage was at 12° C or lower, growth and toxin were not detected after 55 days.[92,243] Thus, although these heat treatments would not inactivate 10^6 spores in the presence of lysozyme, they might be used in combination with refrigerated storage and a limited shelf-life (eg, 42 days) to ensure the safety of food with respect to *C. botulinum* even if the food contained lysozyme.

Before commercial application, these results should be confirmed in specific foods, because foods may differ in their protective effects on spores during heating and may contain a higher concentration of enzymes with lysozyme activity than in these experiments. In some foods, the inclusion of a further controlling factor such as lower pH may be needed to obtain the required protection factor or to reduce the heat treatment or extend the shelf-life; the published information on the effect of combinations of factors[91,92,110,239,243] provides the basis for selecting an appropriate combination.

41.10 CONCLUDING REMARKS

The incidence of *C. botulinum* in some types of environment, such as some enclosed waterways, can be relatively high. In many parts of the world there is little information about the incidence of the organism; even where information is available, the data are relatively sparse. The improvements in methods of detection of the organism and its toxin, and the increasing availability of methods that do not depend on the use of mice, should facilitate studies that would give further information on the probable incidence of the organism in raw foods. This could be important if changes in production and sources of raw foods are likely to result in higher levels of contamination with spores of *C. botulinum* or other bacteria able to produce botulinum neurotoxin. The introduction of fish farming is an example of a change in production of raw food that has, in some conditions, been associated with an increased incidence of *C. botulinum*, and good practices have been published that prevent this problem.

In the case of many processed foods that have a good record of safety, the basis for that safety with respect to *C. botulinum* has not been fully evaluated. Studies to determine the basis of this safety are needed to ensure the continued safety of these products, particularly when gradual changes and variations in composition and processing are introduced.

Changes in methods of food processing and preservation will require evaluation to ensure that the required safety factor with respect to *C. botulinum* is built into the resulting foods. For example, the use of new methods of "commercial sterilization" such as treatment with high pressure and ohmic heating for low-acid foods must be designed to give at least the equivalent of the protection factor at present used for heat treatment of low-acid, canned foods.

The current rapid increase, in parts of Europe and North America, in sales of meals that rely for their preservation primarily on a combination of minimum heat treatment, refrigeration, and limited shelf-life entails a risk of growth of nonproteolytic *C. botulinum* (and of growth of proteolytic *C. botulinum* if products are subjected to temperature abuse). A substantial amount of recent research has been directed toward ensuring the safety of these foods.

Many of the outbreaks of foodborne botulism have been caused by the failure to apply information and safeguards that were well known and well understood by food microbiologists. There is clearly a need to ensure that commercial food producers, including large and small companies, and people who preserve food on a domestic scale, understand and apply the controls necessary to prevent foodborne botulism.

42.1. INTRODUCTION

During the last 100 years, *Clostridium perfringens* has been most closely associated with clinical cases involving gas gangrene. The organism was first associated with food poisoning about 50 years ago and became more prominent following a 1953 paper by Hobbs et al.[103] Until the 1970s the organism was referred to as *Clostridium welchii.*

Although the symptoms associated with *C. perfringens* foodborne illness are relatively mild in healthy adults, deaths have often occurred in the elderly, in particular, those who were institutionalized. A particularly severe form of human intestinal disease caused by type C strains and known as "pig-bel" is discussed further in Section 42.3.2. A number of other disease states are associated with *C. perfringens* including septicemia, uterine infections, anaerobic cellulitis, sudden infant death syndrome, and enterotoxemia in a variety of domestic animals. This review will focus on food poisoning due to *C. perfringens* enterotoxin (CPE) produced by type A strains.

42.2. TAXONOMY AND CHARACTERISTICS OF THE ORGANISM

42.2.1 General

C. perfringens is a Gram-positive, anaerobic, spore-forming, encapsulated, nonmotile, rod-shaped bacterium. Under rapid-growth conditions (glucose-rich media), cells are shorter than in a slow-growth environment (starch-based media). The G-C content of the DNA is from 24 to 27 moles %. Based on analyses of 16S rRNA nucleotide sequences, the closest relative of *C. perfringens* identified to date is *Clostridium pasteurianum*.[31] Although an anaerobe, the organism will tolerate some exposure to air, thus facilitating the laboratory manipulations involved in its enumeration from food samples.

Sporulation is an important property of *C. perfringens* because it is a factor in classification, spores can survive cooking procedures and resume vegetative cell growth if proper conditions are present, and high levels of enterotoxin formation are associated with sporulation.

42.2.2 Toxin Typing

C. perfringens can produce at least 11 separate toxins in addition to an enterotoxin (Table 42–1), although each isolate produces only a specific subset of these. Details of each toxin have been described.[160,245] Strains are divided into five types based on the production of four extracellular toxins: alpha, beta, epsilon, and iota. The majority of strains produce α toxin (lecithinase, phospholipase C). The traditional method of toxin typing of strains involves the neutralization of the toxins with specific antiserum and determination of neutralization by injecting the toxin-antiserum mixture into mice or into the skin of guinea pigs.[191,245,248] The published sequences of the major toxin genes led Daube et al[45] to develop a toxin typing procedure based on the *in vitro* amplification of specific sequences of the major toxin genes. After electrophoresis, the pattern of bands corresponds to the specific toxin type. The chromosomal organization of these toxigenic types is relatively constant, suggesting that phenotypic differences (eg, extracellular toxins) are due to minor changes at the chromosomal level or from the acquisition of extrachromosomal genes.[30]

42.2.3 Serological Typing

In the 1950s, serological typing of the bacteria was first used to investigate outbreaks due to *C. perfringens*. The first 13 serotypes were prepared in the Food Hygiene Laboratory (London) by Hobbs et al[103] and were known as the "Hobbs types," a term still used today, eg, Hobbs 12 (H12). Cherniak and Henderson[33] provided a detailed analysis of the immunological relationships among serotypes 1, 5, 9, and 10. The isolated capsular polysaccharides formed a single precipitation line with their homologous antiserum.

In England antiserum production was almost entirely against outbreak strains, whereas in the United States (US) and Japan *C. perfringens* from a variety of sources, eg, environmental or fecal from healthy individuals, was used. The combination of 75 English, 34 American, and 34 Japanese antisera was used to serotype isolates of *C. perfringens* associated with outbreaks of food poisoning that occurred in the United Kingdom (UK) between 1970 and 1980. A specific serotype was implicated in 64% (of 646) of isolates using the English antiserum alone. Only an additional 5% of strains were typeable using the American and Japanese antisera; thus, only strains from confirmed outbreaks should be used for antiserum production.[252] The procedure for serotyping has been described by Stringer et al[253] who also listed four reasons for serotyping *C. perfringens*:

- to determine whether strains isolated from fecal specimens obtained from different individuals belong to the same serotype
- to determine whether isolates from the incriminated food and fecal specimens belong to the same serotype
- to establish the food involved when several foods have been consumed
- to identify related outbreaks.

Nevertheless, the development of a definitive serological typing scheme has been hindered by the antigenic heterogeneity of strains of *C. perfringens* type A. This has hindered epidemiological investigations. Other criteria exist for confirming the suspected role of isolates of this organism in outbreaks.

42.3 CHARACTERISTICS OF THE DISEASE

42.3.1 Gastroenteritis Caused by Type A Strains

Virtually all outbreaks of foodborne illness due to *C. perfringens* are caused by type A strains. Occasionally a lecithinase-negative strain is isolated from such outbreaks,[25,241] making the isolate, in principle, not *C. perfringens* (Table 42–2).

Typically symptoms of the illness occur 8 to 24 hours after ingesting food containing large numbers of vegetative cells, which have grown in temperature-abused foods—usually meat and poultry items. Diarrhea and severe abdominal cramps are the principal symptoms. Symptoms usually subside without treatment within 24 hours, although residual cramping may persist for an additional 24 to 48 hours. Vomiting and fever are uncommon. Mortality is low

Table 42–1 Soluble Antigens in *C. perfringens* Culture Filtrates

		Occurrence in Filtrates of C. perfringens Types[a]				
Designation	*Activity*	*A*	*B*	*C*	*D*	*E*

and generally occurs in the elderly. Undoubtedly the fact that symptoms are relatively mild has hindered proper epidemiological investigations of sporadic outbreaks, with only large-scale outbreaks prompting thorough investigation. The relatively brief nature of gastroenteritis probably occurs because the toxin preferentially binds to intestinal cells, which are rapidly replaced by normal turnover, and because the diarrhea associated with the illness causes the removal of unbound enterotoxin as well as toxin-containing sporulating cells. The illness is self-limiting and antibiotic therapy is not recommended in most cases. Dehydration, especially in the elderly, is the most important concern.

The enterotoxin responsible for foodborne illness is produced during sporulation of the organism in the small intestine, thus requiring the survival of ingested cells during stomach passage. It is unknown whether an acid tolerance response[59] is induced during this process; however, acid enhancement of sporulation by *C. perfringens* has been demonstrated in the case of at least one strain.[289] In any event it is likely that some lethality results from exposure to stomach acidity; hence the need for large numbers of ingested cells.

Table 42–2 Distribution of the Major Lethal Toxins among Types of *C. perfringens*

Type	*Alpha*	*Beta*	*Epsilon*	*Iota*
A	+	-	-	-
B	+	+	+	-
C	+	+	-	-
D	+	-	+	-
E	+	-	-	+

42.3.2 Related Illnesses

A more severe type of gastroenteritis caused by *C. perfringens* type C occurs among natives of the New Guinea highlands. It is a necrotizing, hemorrhagic jejunitis, commonly called pig-bel and associated with pig feasting.[279] About 70% of the villagers are carriers of the type C strains.[132] Malnutrition is an apparent risk factor because it leads to levels of intestinal proteases that are too low to destroy the toxin. Foods containing protease inhibitors, such as trypsin inhibitors, may prevent breakdown of the toxin in the gut.[131] The illness is rare in Western countries.

More recently a nonfoodborne, gastrointestinal illness of humans associated with *C. perfringens* has been associated with antibiotic use.[19,20] Most patients had received antimicrobials within 4 weeks before symptoms appeared and had high fecal counts of ent⁺ strains of *C. perfringens* as well as enterotoxin in their stools. The antibiotics may have disrupted the normal flora of the gastrointestinal tract sufficiently to allow small numbers of the ent⁺ strains to grow and produce enterotoxin. The situation is strikingly similar to antibiotic-associated diarrhea caused by *Clostridium difficile.*

There have been sporadic reports of foodborne illness due to *C. perfringens* with relatively short incubation periods (< 8 hours).[209,216,231] This suggests a role of preformed toxin or ingestion of sporulating cells. Given sufficient time, the organism can form large numbers of spores and enterotoxin in meat and poultry.[42,47,167,175] The likely adverse sensory qualities of the food in such cases[209] probably contributes to the rarity of such events. Emerging epidemiological evidence incriminates CPE in other human and veterinary disease apart from foodborne illness (Table 42–3).

42.4 MECHANISMS OF PATHOGENICITY

42.4.1 Histopathological Effects

Early studies regarding gastroenteritis caused by *C. perfringens* used viable cultures administered to animals and humans resulting in overt diarrhea. The purification of the enterotoxin led to the demonstration that it is the factor primarily responsible for experimental diarrhea in humans and in a number of animal models. These include pigs,[37] lambs,[93,183] sheep,[183,184,189] calves,[185,186] chickens,[187,188] dogs,[14] rats,[159,162,165] rabbits,[50,92,163–165,183,234,253] guinea pigs,[183] mice,[173,290] monkeys,[50,94,272] and humans.[256] Eight to 10 mg of purified CPE were required to induce symptoms in humans,[240] provided the gastric juice was neutralized with sodium bicarbonate.

The enterotoxin accumulates within the sporulating cells. Lysis of the cells releases the toxin, which then binds to epithelial cells. The brush border (microvillous membrane) of villous tip epithelial cells is the primary site of action of the enterotoxin. Histological studies of enterotoxin-treated ileal loops of rabbits reveal desquamation of epithelial cells at villous tips.[165] Tissue damage is detectable within 15 minutes of exposure of rabbit ileal loops to CPE.[227] The normal folded configuration of the brush border is lost and large quantities of membrane and cytoplasm are lost to the lumen. Scanning electron micrographs reveal localized morphologic damage to villous tips and a covering of rounded blebs on the tips (Figure 42–1). The toxin also causes "bleb" formation in rabbit villus epithelial cells (Figure 42–2) and in cultured Vero cells.[161] At least in the case of rabbits, the colon is relatively insensitive to the enterotoxin even though it binds well to rabbit colonic cells.[161] The sensitivity of the rabbit's small intestine to the enterotoxin increases from the upper duodenum downward, with the terminal ileum being the most responsive.[164] Although mode of action studies of CPE-induced alterations of morphology have used Vero (African green monkey kidney) cells, similar changes occur in mammalian intestinal epithelial cells.[155]

42.4.2 Molecular and Cellular Effects

The development of an *in vitro* model system for studying the enterotoxin has led to an understanding of its mode of action at the cellular level. Vero cells have been used widely for these studies, although other cell lines also have been used as models.[107,110,161,242] By contrast, Chinese hamster ovary cells are insensitive to the enterotoxin.[283] Structure and function mapping studies of CPE have identified the N-terminal region as involved with insertion and cytotoxicity and the C-terminal end with binding (Figure 42–3).[152] Following detailed studies of the effect of the enterotoxin, McClane and coworkers established the sequence of events in the action of the toxin (Figure 42–4). The initial calcium-independent event involves binding of the toxin to its receptor, a 50 kDa membrane protein.[286] In contrast to the situation with *Escherichia coli* labile enterotoxin and *Vibrio cholera* enterotoxin, no role has been identified for ganglioside GM_1 from rabbit intestinal brush border membranes in the binding of *C. perfringens* enterotoxin.[286] The CPE forms a large complex with membrane proteins and remains bound to the membrane without entering the cell.

CPE initially causes cells to become permeable to the influx and efflux of a variety of molecules of less

than 200 daltons, such as ions and amino acids,[149,151,153] perhaps by the formation of pore structures. Osmotic stabilizers protect against such CPE-induced permeability changes.[151,156] Events after small molecule permeability alterations appear to be secondary consequences and include inhibition of DNA, RNA, and protein synthesis, and bleb formation.[155] Water follows the ion influx into the cytoplasm causing the plasma membrane of treated cells to stretch, forming blebs. The change in permeability to small molecules leads to the loss of macromolecular precursors and loss of viability. In cases of foodborne illness, this presumably leads to intestinal cell lysis and desquamation of intestinal cells from villous tips. Loss of fluids and electrolytes corresponds to the diarrheal symptoms associated with the illness. The molecular events associated with CPE action on mammalian cells have been recently described in detail.[153,154]

42.4.3 Characteristics of the Enterotoxin

The enterotoxin was purified in the early 1970s and its amino acid sequence subsequently determined.[44,154,275] In the case of strain NCTC 8798, the toxin is composed of a single polypeptide with a unique sequence of 319 amino acids with a molecular weight of 35,317 and a pI of 4.3.[44,152] The toxin aggregates from solution at concentrations above 0.5 mg ml^{-1} at 4° C, perhaps due to its high hydrophobic amino acid content (43%).[73]

The enterotoxin loses its activity after treatment with pronase and subtilisin.[160] Limited exposure to trypsin and chymotrypsin actually increased its biological activity,[70,75] suggesting its possible activation in the small intestine during foodborne illness. A loss of 36 and 25 amino acids from the N-terminus occurs in the case of chymotrypsin and trypsin treatment, respectively. The toxin is also easily inacti-

vated by heat. In saline, exposure to 60° C for 5 minutes destroys biological activity.[177] Others have reported a 90% loss in biological activity within 1 minute at 60° C in buffer, pH 6.8.[71] Serological activity is affected more slowly, with 20% remaining after heating at 60° C for 20 minutes. Serological activity is lost more rapidly at pH <6.0. In food samples, about 12% of serological activity destroyed by heating at 60° C can be restored by treatment with urea at room temperature for 1 hour.[177] Other workers reported that CPE, heated at 55° C for 1 minute (70% loss of activity) regained 50% of original biological activity after 4 days.[71] CPE stored at 37° C for 7 days or at –20° C loses biological but not serological activity;[167] however, neither biological nor serological activity is affected by storage at 4° C for several weeks in 0.02 M phosphate buffer, pH 6.8.[75] About 5% to 10% of the toxin's original activity is lost each time it is thawed; therefore, lyophilization is the preferred method of storing CPE.

Maximum ultraviolet absorption occurs at 276 nm. The extinction coefficient at pH 6.8, $E_{1\mathrm{cm}}^{0.1\%}$ at 276 nm, of CPE, is 1.33.[74] In 0.02 M phosphate buffer, pH 6.8, its maximum solubility at 25° C is 3.94 ± 0.22 mg ml^{-1}.[74] Enterotoxin has also been detected in *C. perfringens* types B, C, and D.[147,239,273] Its properties are similar to those of enterotoxin of type A strains.

There have been few studies on the immune response to CPE. Like staphylococcal enterotoxin A, CPE is a superantigen that stimulates large quantities of T-cells,[21] although it is not known whether this is linked to enterotoxicity or cytotoxicity. Analysis of deletion mutants indicates that the minimum size CPE fragment that retains cytotoxicity appears to be CPE amino acids 45 to 319.[118]

42.4.4 Production and Isolation of *C. perfringens* Enterotoxin

In vitro Synthesis

In the laboratory, crude enterotoxin is obtained from extracts of late-stage sporulating cells. Many strains notoriously are reluctant to sporulate and sporulation is distinctly strain- and medium-dependent. Cooked meat medium (CMM) is commonly used for growth of the organism, and stock cultures can be maintained frozen in this medium for many years. The level of sporulation in CMM is insufficient for high CPE yields and the medium of Duncan and Strong,[49] or minor modifications of it,[40,84,112,270] have been the most widely used. The medium is composed of yeast extract, peptone, starch, sodium thioglycollate, and sodium phosphate. Replacing the starch with raffinose increases the sporulation and CPE levels of some strains.[128,270] In the presence of raffinose, the incubation temperature can be increased from the standard 37° C to 43° C. This shortens (by about 2 hours) the time required for (but not the extent of) maximum levels of sporulation and CPE formation.[61] Certain methylxanthines (caffeine, theobromine, and theophylline)[112,127,225] and bile salts[98] also can enhance the level of sporulation. Other factors that may affect the level of sporulation include the use of overnight vs log-phase cultures and the amount of inoculum. These must be determined empirically; a single set of conditions may not promote sporulation by all strains.

Several solid sporulation media also have been described.[247,269] These could be useful for the direct detection of sporulating, enterotoxin-producing colonies, eg, by enzyme-linked immunosorbent assay

(ELISA); however, the availability of colony hybridization techniques using DNA probes for the *in situ* detection and enumeration of vegetative cells carrying the *cpe* gene[9] has diminished the need for solid sporulation media.

Certain situations require a defined sporulation medium; for example, metabolic studies of the sporulation process,[48] purification of extracellular products produced during sporulation,[192,193,233] or radioactive labeling of CPE.[72,141] In addition, the nutritional requirements for sporulation and enhancers of sporulation, such as methylxanthines, can be more accurately assessed using a defined medium.[121] For these purposes, the defined sporulation medium of Sacks and Thompson[224,226] is quite suitable, although as with the complex media, not all strains respond with a high percentage of sporulating cells. This medium and other defined media[66,207,233,264] are based on earlier formulation by Boyd et al[22] for vegetative cell growth.

The pattern of CPE formation during growth in a complex medium is now well established.[120,251] In defined media, the kinetics are similar but the lag phase is longer [Labbé, unpublished]. Briefly, at 37° C, heat-resistant spores appear after between 3 and 4 hours and increase rapidly, reaching maximum numbers after 7 hours, typically between 2×10^7 ml^{-1} and 5×10^7 ml^{-1}, remaining at that level for at least 48 hours. Intracellular CPE formation (measured as a proportion of cell extract protein) parallels spore formation decreasing after about 10 hours as sporangial autolysis occurs. It is at this point that CPE is detectable in the culture fluid. In cases of foodborne illness, this would correspond to its release in the lumen of the small intestine and subsequent action on microvilli.

The pattern of *cpe* gene transcription and translation during sporulation is shown in Figure 42–5. During exponential growth no CPE protein can be detected and only trace amounts of *cpe* mRNA are seen. The induction of *cpe* mRNA and CPE protein occurs simultaneously about 1 hour after the end of exponential growth (T_0) and rises sharply throughout stationary phase. This indicates that the induction of *cpe* gene expression is an early stationary-phase event. This is in line with the earlier conclusions of Duncan et al[52] who isolated Spo$^-$ mutants and showed that mutants blocked at stage 0 fail to make CPE, while those blocked at later stages, III to V, were able to do so. Thus it is likely that *cpe* gene expression is induced after stage 0 and before stage III (no stage II mutants were isolated).

Some strains of *C. perfringens* that form high concentrations of enterotoxin form an inclusion body in the sporangium (Figure 42–6);[53,262] this is composed of CPE and has biological activity.[139,140] This aggregated CPE is in addition to soluble toxin present in cell extracts. Its role in human illness is unclear.

Purification of Enterotoxin

Of the methods proposed for the purification of CPE, that using ammonium sulfate precipitation of sporulating cell extracts followed by gel filtration[74] has been most widely used. The soluble, intracellular protein concentration of several sporulating strains can consist of up to 30% to 40% CPE,[128] although for most outbreak strains the level is about half this amount. The use of such strains together with growth at 43° C has yielded a protocol for CPE purification within 48 hours.[97]

Occasionally some toxin preparations contain a minor band after purification[12,55,229] as visualized by polyacrylamide gel electrophoresis (PAGE). This minor band possesses weak biological and serological activity. The molecular weight, but not the charge, is the same as that of the major band, perhaps due to endogenous protease activity.[139,195] The use of the protease inhibitors EDTA and phenylmethylsulfonylfluoride and low temperatures prevents such artifacts.[97,195]

The efficacy of protein purification protocols is confirmed usually by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (SDS-PAGE). It has been shown repeatedly that this procedure results in the aggregation of CPE with the appearance of several higher molecular weight bands.[43,56,69,106,158,205,223,230] However, no aggregation of the CPE is seen below 15 µg ml^{-1}.[222] PAGE, under nondenaturing conditions, does not result in such anomalous aggregation.

Relationship of Enterotoxin Formation to Sporulation

The pioneering work of Duncan et al. in *C. perfringens* research included the isolation of mutants of an enterotoxin-positive strain blocked developmentally at various stages of sporulation.[52] Sporulation stages are numbered from 0 (vegetative cell) to VII (sporangial autolysis). The ability or inability of these mutants to produce CPE originally led to the conclusions that CPE appears between stages 0 and III and it is a sporulation-specific gene product. A close correlation has long been known between the intracellular accumulation of CPE and sporulation; nevertheless, subsequent studies using serologic techniques demonstrated low levels of CPE in vegetative cells of *C. perfringens*.[65,76] This could have resulted from reactivity to a 48-kDa,

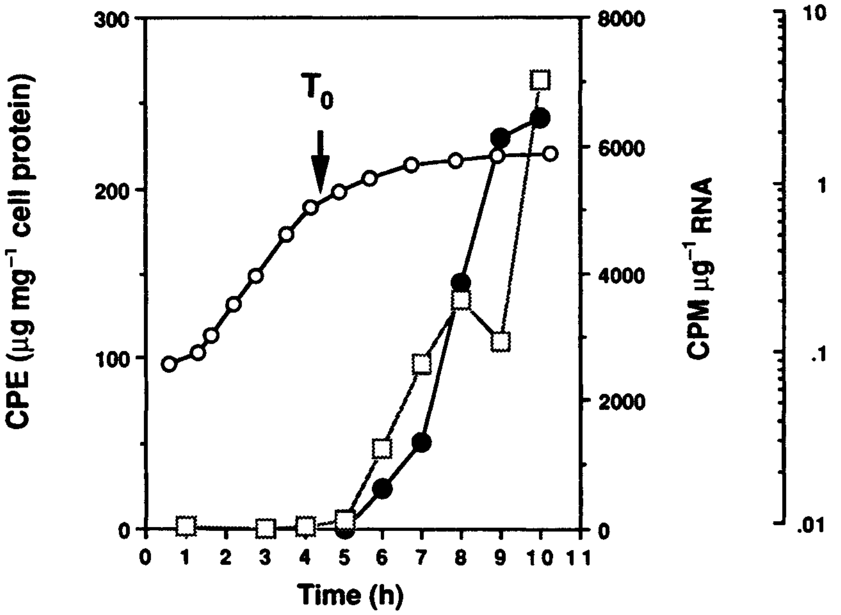

Figure 42–5 Synthesis of *cpe* mRNA (Squares) and *C. perfringens* Enterotoxin Protein (Solid Circles) during Growth (OD_{600} [Open Circles]) of *C. perfringens* NCTC 10240 at 37° C in Modified Duncan-Strong Sporulation Medium. *Source:* Reprinted with permission from S. Melville, R. Labbé, and A. Sonenshein, Expression from the *Clostridium Perfringens* CPE Promoter in *C. Perfringens* and *Bacillus subtilis*, *Infection and Immunity*, Vol. 62, p. 5554, © 1994, American Society for Microbiology.

CPE-related protein that has been shown to exist in vegetative cells;[223] however, using a more sensitive Western blot assay, Czeczulin et al[44] did detect exceedingly small amounts of CPE in cell extracts of ent+ vegetative cells. No biological activity was detected. Further, cell lysates from recombinant *cpe*-positive *E. coli* were shown by quantitative Western blot analysis to contain moderate amounts of CPE.[44]

The CPE content in sporulating cells can amount to a significant portion of the soluble cell extract protein in certain strains,[61,121,128] but knowledge of the function of CPE remains elusive. Earlier proposals that CPE may serve as a structural spore coat protein appear unlikely because relatively small amounts of CPE are associated with the spore, perhaps as a result of having been "trapped" during spore development.[222] Furthermore, virtually all enterotoxin-negative strains are capable of sporulation. It seems more likely that the *cpe* gene plays no role in sporulation but is activated by transcriptional factors that also control sporulation genes. Studies of *cpe* regulation at the transcriptional level may provide an explanation for the high levels of CPE produced during sporulation. In summary, very low levels of enterotoxin may be formed by vegetative cells, but high concentrations are produced only in association with sporulation, and this is unquestionably involved in causing foodborne illness.

Genetics of Enterotoxin Formation

Recent years have seen the cloning, sequencing, and other genetic studies on *C. perfringens* toxins, including α toxin, θ toxin, ε toxin, ι toxin, κ toxin, β toxin, sialidase, and hyaluronidase.[220] These have been used in vaccine and virulence studies. The physical map of one *C. perfringens* strain (CPN50) now comprises almost 100 markers.[34,36,117] The complete *cpe* gene from two CPE-positive strains has been cloned.[38,44] The availability of *E. coli-C. perfringens* shuttle plasmids,[10,214,243] reporter systems,[28,150,200] methods for electroporation-induced transformation,[6,232] and other genetic methods have shown that CPE synthesis is regulated at the transcriptional level. The *cpe* gene was found at the same chromosomal locus in three strains associated with food poisoning;[38] whereas, in 20 strains originating from domestic livestock the *cpe* gene was located on a large episome. This suggests the possibility of intergeneric transfer and, in fact, conjugation and mobilization of large plasmids in *C. perfringens* is well documented.[24,219] Similar to the variation in location of the *cpe* gene, two types of promoter regions have been reported to exist.[171] The cloning and sequencing of the entire *cpe* structural gene and its location on the restriction map of the *C. perfringens* chromosome[30] should result in the rapid elucidation

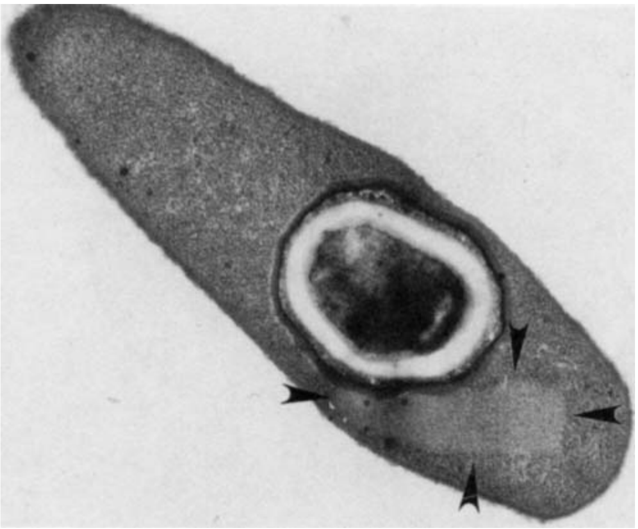

Figure 42–6 Transmission Electron Micrograph of *C. perfringens* Showing Inclusion Body during Sporulation of Strain NCTC 8679, × 47,000. of factors controlling the expression of the *cpe* gene. The reader is referred to recent articles detailing the molecular genetics of *C. perfringens* in general[34,35,142,218,219] and CPE in particular.[73,172]

42.5 INCIDENCE OF THE ORGANISM

42.5.1 In the Environment

Types B, C, D, and E can be considered parasites of domestic animals and do not survive in soils, dying out within a few months if added to soil samples, presumably because they are unable to compete with type A strains and other microflora. By contrast, type A strains are part of the microflora of both soil and intestinal tracts. Their numbers in soil are estimated to be several thousand per gram. The organism can be found also in low numbers in marine sediments, those present probably representing recent pollution.[148,227]

42.5.2 In Foods

Numerous surveys have been conducted on the incidence of *C. perfringens* in raw and processed foods; the results of a number of these are shown in Table 42–4. Raw protein foods of animal origin are far more likely to contain vegetative cells or spores of the organism than are processed foods. These reports indicate widespread occurrence of the organism in meat and poultry. About 50% of raw ground beef contains the organism.[60,129] *C. perfringens* was isolated from 29%, 66%, and 35% of beef, pork, and lamb carcasses, respectively,[244] although the numbers, obtained adjacent to the anus, were surprisingly low (< 20 per 100 cm^2). Intestinal tissues prevent the release of bacteria into the body cavity for several hours after death,[64] indicating that blood and lymph vessels do not normally offer a pathway for microbial invasion from the intestine. In addition, adequate rest and starvation before slaughter can dramatically reduce internal contamination of carcasses.[181]

Although not commonly involved in foodborne illness, fish (body surfaces and alimentary canal) were found positive for *C. perfringens.*[264] In a survey of vacuum-packed fish products, 67% were positive for clostridia, predominately *C. perfringens.*[102]

C. perfringens was isolated from 80% of 54 different spices and herbs.[46] The presence of this organism in herbs and spices, especially in the spore state, creates a hazard because such products are added often to large amounts of meat and poultry. Spores can survive cooking, and slow cooling could result in the growth of large numbers of vegetative cells.

Most surveys of the incidence of *C. perfringens* have not identified the enterotoxin-producing potential of the isolates. This is increasingly important because, in the case of nonsymptomatic animals, only 6% of strains possessed the *cpe* gene.[276] Only about 60% of food and fecal isolates (from 186 outbreaks) hybridized with synthetic DNA probes for the *cpe* gene,[277] suggesting that strains that could not produce CPE had been isolated originally.

42.5.3 In Feces

Up to 39 different *Clostridium* species have been isolated from human feces with *C. perfringens*, typically enterotoxin negative, being the most common isolate.[63] Some early studies focused on the heat-resistant *C. perfringens* strains (those whose spores survive 100° C for 1 hour). Surveys of the *C. perfringens* levels, regardless of type of spore heat resistance, indicate that most adults harbor the organisms, with median counts typically in the range of 10^3 to 10^4 g^{-1} feces;[91,251,260] however, spore concentrations of up to 10^9 g^{-1} (median: 10^5 g^{-1}) have been reported in healthy adults from Japan and from the elderly in Japan and the UK.[5,178,251] Such high counts

have been found also in patients with infectious diarrhea not associated with food poisoning.[130] A detailed review of the clostridial flora in humans was presented by George and Finegold.[63]

In Europe the presence of *C. perfringens* has been used to supplement water quality information,[192] and the World Health Organization (WHO) has recommended it as a useful indicator of fecal pollution of water.[108] Fecal coliforms are poor indicators of the presence of human bacterial viruses in drinking water. *C. perfringens* is a suitable indicator for the inactivation and removal of viruses in drinking water[196] in particular and for evaluating the effectiveness of wastewater and sludge treatment systems in general.[101] Finally *C. perfringens* (presumably in the spore state) was shown to be a useful indicator of distribution of sewage sludge on the ocean floor[99] where conditions (2° C, 250 atmosphere [25.3 MPa]) are presumably unsuitable for coliforms and fecal streptococci. These applications have been facilitated by the development of rapid membrane filtration techniques for detection and isolation, combining high incubation temperatures, biochemical characterization, and antibiotics.[8,18]

42.6 EPIDEMIOLOGY

C. perfringens food poisoning is a worldwide problem, present wherever meat and poultry, in particular, are consumed regularly. The incidence is widely under-reported due to the perceived mild nature of the illness and differences between countries in their surveillance arrangements (Table 42–5). The number of outbreaks reported in England and Wales, where surveillance of this disease generally is more closely integrated, albeit informally, far exceeds that in the US, where reporting of this disease is largely uncoordinated nationally. The small number of confirmed outbreaks from the US in 1987 highlights the lack of vigilance and low priority associated with this illness by public health authorities of one country alone. WHO, as part of its Surveillance Program for the Control of Foodborne Infections and Intoxications in Europe, collects data from outbreaks in many countries; however, for most countries *C. perfringens* is not specifically reported.

As mentioned above, meat and poultry are the most common vehicles; given the organism's fastidious growth requirements and its presence in these

products, this is not surprising. Food service establishments such as restaurants, hospitals, factories, prisons, schools, and caterers are the most likely sources of acquiring the illness. This results from needing to cook large amounts of food well in advance of serving.

42.7 FACTORS AFFECTING SURVIVAL IN FOOD

The two outstanding characteristics of *C. perfringens* that invariably contribute to its role in foodborne disease outbreaks are its rapid growth at temperatures of 43° to 46° C and its spore-forming ability. Factors affecting the growth and survival of the organism are dependent on whether the vegetative cell or spore is being considered; thus, each cell form will be considered separately.

42.7.1 Vegetative Cells

Temperatures for Growth

C. perfringens is able to grow in the range of 15° to 50° C. Growth at 15° C in aerobic or vacuum-packed cooked beef occurred only after several days,[39,114] but other workers have shown that *C. perfringens* (ent$^+$ strains) can grow in cooked roast beef at 12.8° C (55° F) when coinoculated with *Pseudomonas fragi*, presumably due to oxygen consumption by *P. fragi*.[100] A modified atmosphere (75% CO_2, >2% O_2, balance N_2) prevented growth of *C. perfringens* at 12.8° C (but not at 26.7° C) when coinoculated with *P. fragi*. Modified atmosphere packaging cannot be used effectively at room temperature to inhibit *C. perfringens* and cannot be used as a substitute for refrigeration.

Unique among foodborne pathogens, *C. perfringens* has a relatively high optimum growth temperature, 43° to 46° C, depending on the strain, although Willardsen et al[285] described one ent$^+$ strain as having a slightly shorter generation time (G_t) at 41° C than at 45° C. No lag was reported at 46° C for cells grown in meat although at 35° C there was a 2 to 4 hour lag period.[79]

G_t of approximately 9 minutes have been reported for ent$^+$ strains or for a composite of ent$^+$ and ent$^-$ strains growing in raw or cooked ground beef.[126,284,285] These times are among the shortest for any bacterium, and the ability for such rapid division has obvious public health importance. Even at 37° C one ent$^+$ strain had a G_t of 10 to 12 minutes in cooked chicken or turkey, while the same composite of strains had an average G_t of 30.8 minutes in cooked ground beef at 37° C.[285]

Few strains of *C. perfringens* grow at 49° C[79] and no growth has ever been reported at 52° C or above. However, apparent thermal adaptation by this organism can occur because each of two ent$^+$ strains showed more than a two-fold increase in $D_{57° C}$ value when the growth temperature was increased from 37° C to 45° C.[221]

Next Page

The literature up to 1979 describing the effects of temperature on growth has been reviewed by Craven.[39] The important points that emerge are that at static temperatures between 33° C and 49° C, G_ts of < 20 minutes can be expected for *C. perfringens* growing in food and that vegetative cells are inactivated readily at 55° C and higher. It is unknown whether the generation times of ent$^+$ strains as a class differ from those of ent$^-$ strains. Labbé and Huang[126] were unable to establish such a difference, although only two strains from each group were used.

In comparison with growth at static temperatures within the optimum temperature range, the possibility of growth during cooling has received less attention. To minimize microbial hazards, government agencies specify cooling parameters for food. For example, the U.S. Food and Drug Administration recommends all food be cooled from 60° C to 5° C in 6 hours or less.[275] No growth of a three-strain composite of spores of *C. perfringens* occurred in pasteurized, cooked beef cooled from 54.4° C to 7.2° C in 15 hours or less,[115] although a several log increase did occur if the cooling period was extended to 18 hours.

Rapid growth of two ent$^+$ strains of *C. perfringens* occurred at 28° C in anaerobically packaged cooked, ground turkey, with the numbers increasing by more than 5 log cycles within 9 hours[113] or, in the case of ground beef, by almost 3 log cycles within 18 hours (no increase after 12 hours).[111] On the other hand, refrigerated (4° C), aerobically or anaerobically packaged cooked ground beef temperature-abused at 28° C for 6 hours did not support the growth of *C. perfringens.*[111] Similarly, no growth from spores occurred within 150 minutes in cooked, ground beef inoculated at 60° C and cooled to 15° C at a falling rate of 15° C per hour.[235]

Taken together, the results suggest that *C. perfringens* may grow to unsafe levels in foods, including *sous vide* products, if such foods are temperature-abused for relatively long periods, but short periods of temperature abuse of refrigerated meat do not necessarily result in hazardous cell levels.

Low-Temperature Storage

C. perfringens is notably sensitive to low-temperature storage.[255,266] Stationary-phase cells are more resistant to the effect of cold shock than log-phase cells, which were reduced by 80% to 90% within 60 minutes when held in 0.1% peptone at 4° C.[266] Similarly, more than 90% of cells were inactivated following frozen storage at -17.7° C for 30 days in a starch paste, and even more in buffer.[258] Other studies of *C. perfringens* in food products held at -20° C for 17 days or at -29° C for 28 days resulted in a survival rate of 0.1% and <1% respectively.[82,266]

Oxidation-Reduction Potential (E_h)

C. perfringens will not produce colonies on agar exposed to air. In liquid media, the E_h is maintained at suitable levels by removal of oxygen and the inclusion of reducing agents such as cysteine and sodium thioglycollate, and by the use of low concentrations of agar to minimize oxygen diffusion. Simply steaming liquid media for a few minutes is effective in removing oxygen. Multiplication of *C. perfringens* was inhibited in the presence of oxygen in both the negative and positive ranges of E_h;[278] however, in the absence of oxygen multiplication occurred at both negative or positive E_h. The E_h levels of laboratory media are typically from +200 mV to +250 mV.[11,169] The upper limit that inhibits growth is near +350 mV[197] depending on strain, metabolic state, and size of inoculum. Intense reducing conditions are established by the organism during logarithmic growth, probably due to the presence of low E_h substances such as ferredoxin. Final levels can reach below -400 mV.

pH

C. perfringens grows best at pH levels of between 6.0 and 7.0 with a range of between pH 5.0 and 9.0. The lower levels are reached in laboratory media containing readily fermentable carbohydrates. Clearly, some inactivation and/or injury of cells occurs during stomach passage due to the low pH levels (~ 2) encountered; however, the metabolic state of the cells is important because young, actively growing cultures are more susceptible to low pH than are stationary-phase cells.[57,90,289] The buffering capacity of proteins and the sheer bulk of the ingested food no doubt allows ent$^+$ cells to survive and subsequently sporulate in the small intestine. A recent report[289] indicated that acid exposure (pH 2.0, 30 minutes) actually enhances enterotoxin production (by four of five ent$^+$ strains).

Water Activity (a_w)

Typically the limiting a_w for growth of microorganisms depends on related conditions such as temperature, pH, and the solute used to adjust the a_w. Compared with *Staphylococcus aureus*, *C. perfringens* is not especially tolerant of low a_w. The lowest a_w supporting growth is between 0.97 and 0.95 using sucrose or sodium chloride (NaCl) respectively,[116] 0.93 with glycerol,[116] and 0.96 with glucose.[257] An awareness of limiting a_w would be important in newly introduced foods, such as intermediate-moisture foods.

Curing Salts

A level of 7% to 8% NaCl is required to prevent the growth of most strains of *C. perfringens*, although some inhibition occurs at levels of 5% to 6%.[39,68,168,213] In the case of sodium nitrite, levels of between 60 and 2560 ppm inhibit growth in filter-sterilized media, significantly less if nitrite is autoclaved with the test medium (due to the "Perigo effect").[199,208] The action of nitrite against *C. perfringens* has been reviewed by Craven.[39] Not surprisingly, lower concentrations of curing salts are required to inhibit growth when they are used together. For example, the inhibitory nitrite level decreased from 300 to 25 µg ml^{-1} when the amount of NaCl was increased from 3% to 6%.[213] Cured meats rarely are vehicles for outbreaks of illness due to this organism. For 1978 to 1992, only two such outbreaks (due to ham) were reported to the U.S. Centers for Disease Control and Prevention.

42.7.2 Spores and Sporulation

Effect of Temperature on Sporulation and Spore Inactivation

In complex culture media at 37° C, maximal levels of heat-resistant spores are attained usually within 7 hours;[123] in model food systems about twice as much time is required.[175] The higher the sporulation temperature, the greater the spore heat-resistance, an effect previously noted with *Bacillus* species.[133] For example, $D_{95°C}$ values (time for inactivation of 90% of the population at a specified temperature) of one ent$^+$ strain increased from 116 minutes (sporulation at 37° C) to 200 minutes (sporulation at 43° C).[61] Earlier reports[124] that *C. perfringens* cannot sporulate well at its optimal growth temperature (43° C to 45° C) have been disproven. Starch had been the principal carbohydrate in these investigations and α-amylase of most ent$^+$ strains was inhibited at the higher temperatures.[62] In the presence of raffinose (in place of starch), sporulation of many strains proceeds rapidly. This has been used to develop a rapid method for *in vitro* enterotoxin formation and purification.[97]

The ability of spores of *C. perfringens* to survive cooking is a principal contributing factor in its involvement in foodborne illness. Spores of type A strains vary widely in their heat-resistance. Significant differences in D-values exist between heat-sensitive (HS) and heat-resistant (HR) spores.[212] For example, in one study, the $D_{95° C}$ values for the HR group were between 17.6 and 63.0 minutes compared with between 1.3 and 2.8 minutes for the HS strains.[7] This explains, at least in part, the more frequent occurrence of the HR strains as the responsible agents in outbreaks; however, equally important, few HS strains produce CPE. Of 20 HR strains examined, only three were CPE-negative by reverse, passive latex agglutination (RPLA) (whether the CPE-negative strains had sporulated was not stated);[7] whereas of 17 HS strains, only one was RPLA-positive. A similar inverse relationship was noted between spore heat-resistance and lecithinase activity.[282]

In addition to genetic differences between strains, other factors that must be considered in comparing spore heat-resistance are the sporulation temperature and the medium in which the spores are produced and heated.[3,41,212,282] For example, heat resistance is greater in cooked meat than in water. It is important to use uniform conditions for comparing spore heat-resistance; this includes the use of clean spores (ie, free of their sporangia and vegetative cells). The D-values from a number of studies have been summarized elsewhere.[123]

As with spores of *Bacillus* species, spores of *C. perfringens* will germinate optimally only if they are mildly heated;[7] 75° C for 10 minutes is used typically. HR and HS spore strains respond differently to heat activation. In one study, about 50% of spores of the HS group grew without prior heat treatment compared with 0.13% to 3.6% for HR strains.[212]

Recovery of Spores from Thermal Injury

Spore injury and recovery is an important food safety issue. Unique among bacterial spore formers, *C. perfringens* (both HR and HS spore types) and *Clostridium botulinum*[198] spores can be recovered after thermal injury by inclusion of lysozyme in the plating medium.[32,54] Spore recovery rates of between 1% and 8% were achieved in the presence of 1 µg lysozyme ml^{-1} of plating medium compared with between 0.0001% and 0.0007% in its absence. Examples of the effect of lysozyme on D-values (time required for 90% reduction in viable counts) of *C. perfringens* spores are shown in Table 42–6. A similar though less dramatic phenomenon occurs using *C. perfringens* concentrated, supernatant fluid in place of lysozyme.[54] The responsible agent in this case was named initiation protein (IP). Both lysozyme and IP act at the level of germination and mimic the native spore-lytic enzyme[67] that is inacti-

vated by the heating process.[263] The concern here is that lysozyme is a recognized food additive, and many foods naturally contain enzymes with lysozyme activity.

42.8 ISOLATION OF *C. PERFRINGENS* AND DETECTION OF ENTEROTOXIN

42.8.1 Criteria for Outbreaks

In addition to high numbers of viable cells in suspect foods, the presence of elevated fecal spore counts (those that survive heating at 75° C for 20 minutes) is also a diagnostic criterion. This was evaluated by assaying 66 stool specimens from nine outbreaks.[85] Using tryptose-sulfite-cycloserine (TSC) agar mean counts from outbreak stools were 1.4×10^6 cfu g^{-1} compared with 9.5×10^3 cfu g^{-1} from normal stools. Similar counts were obtained with sheep blood agar (without antibiotics). Only a minimal reduction in the spore count occurred following frozen storage of stools.

Current Public Health Laboratory criteria for establishing an outbreak of *C. perfringens* type A food poisoning include any one of the following:

- $> 10^6$ spores g^{-1} feces from ill individuals
- $> 10^5$ cells g^{-1} in incriminated food
- the presence of the same serotype in all individuals in an outbreak
- demonstration of the same serotype of *C. perfringens* in both contaminated food and feces

At least two problems have compromised three of these criteria: feces from many elderly individuals normally contain high numbers of *C. perfringens* spores and at least 25% of isolates do not react with available antisera. This has led to the view that the occurrence of outbreaks should be confirmed by direct detection of enterotoxin in feces of patients.

42.8.2 Cultural Methods for Detection

Detection

To avoid cold injury, food samples that require more than a 2-day storage should be mixed with a buffered glycerol salts solution to give a final concentration of 10% glycerol and be frozen as rapidly as possible to $< -50°$ C (eg, as on dry ice).[125]

The earlier efforts at development and use of plating media have been reviewed elsewhere.[122] The medium currently recommended in North America is TSC agar[87,88] in which *C. perfringens* appears as black colonies following the reduction of sulfite to sulfide. Its usefulness was confirmed by the work of Hauschild et al[95,96] who, at the request of the International Commission on Microbiological Specifications for Foods, evaluated many media proposed for enumeration of *C. perfringens*. The egg yolk–free variation (Table 42–7) is recommended because it is just as effective, simpler, and is a pour plate method. Incubation is at 37° C in anaerobic chambers under nitrogen or other anaerobic gas mixtures. As mentioned above, a count of $>10^5$ cells g^{-1} of food is sufficient to implicate suspect foods.

In the UK, surface-inoculated (horse) blood agar containing neomycin is used as well as TSC. The advantage of neomycin blood agar is that hemolysis by colonies is readily determined; however, neomycin can inhibit the recovery of some strains of this organism,[246] and neomycin-blood agar is not recommended for examining normal food samples in which the organism is present only in low numbers.

The simplicity and sensitivity of iron milk medium (IMM) should be mentioned. This most probable number (MPN) method uses pasteurized, whole milk supplemented with 2% iron powder.[249] Selection is based solely on the rapid growth of *C. perfringens* at 45° C and the typical "stormy fermentation" reaction within 18 hours, during which acid from lactose fermentation rapidly coagulates the milk and is followed by fractionation of the curd into a spongy mass. Confirmation is based on the acid phosphatase test.[1] Similar counts of *C. perfringens* were obtained from environment and food samples using TSC medium or the IMM method.[2,249] The IMM method for detection of *C. perfringens* in shell-

Table 42–7 Media for Enumeration and Confirmation of *C. perfringens* (Ingredient 100 ml^{-1})

Egg Yolk-Free Tryptose-Sulfite-Cycloserine Agar[a]	*(g)*	*Motility-Nitrate Medium*	*(g)*	*Lactose-Gelatin Medium*	*(g)*
Tryptose (Difco)	1.5	Beef extract	0.3	Tryptose (Difco)	1.5
Yeast extract	0.5	Peptone	0.5	Yeast extract	1.0
Soytone (Difco)	0.5	KNO_3	0.5		
Sodium metabisulfite	0.1	Na_2HPO_4	0.25	Na_2HPO_4	0.5
Ferric ammonium citrate	0.1	Galactose	0.5		
Agar	2.0	Glycerol	0.5	Gelatin[b]	12.0
pH adjusted to 7.6		pH adjusted to 7.3		pH adjusted to 7.5	
Cycloserine[c]	0.04	Agar[d]	0.3	Phenol red[e]	0.005

[a] Medium is the same as Shahidi Ferguson Perfringens (SFP) agar base (that contains no cycloserine) and is available commercially.

[b] Dissolved separately in 60 ml H_2O at 50 to 60° C.

[c] One ml of a 4% filter-sterilized solution added after pH adjustment and sterilization.

[d] Added after pH adjustment, then boiled to dissolve.

[e] Added as a solution after pH adjustment.

fish has been adopted as first action by the Association of Official Analytical Chemists (AOAC) International.[1]

A method that uses lactose-sulfite (LS) broth and incubation at 46° C was proposed for rapid enumeration and identification of *C. perfringens* without further confirmatory tests.[182] It was found to be superior to TSC for enumeration of small numbers of the organism in a variety of foods.

Most recently a blood-free, egg yolk medium, BCP (*Bacillus cereus/C. perfringens*) was developed and shown to be equal or superior to TSC for unstressed (fresh, cooked-meat cultures) or injured (cold-shocked) cells respectively.[105] Counts from routine fecal samples or from infectious diarrhea were similar to those obtained on blood agar plus neomycin. The hydrogen peroxide degraders, catalase and pyruvate, each promoted the growth of several injured strains. Unfortunately, commercial egg yolk emulsion was not a satisfactory substitute for yolks prepared from fresh eggs.

Confirmatory Tests

The possible presence of other sulfite-reducing clostridia on TSC medium requires the confirmation of a representative number (about 10) of isolates. The recommended media for this purpose are tubes of motility-nitrate and lactose-gelatin media. Details on their use are described elsewhere.[81,125,215] Reported counts are obtained by multiplying the total count by the fraction of isolates that are confirmed as gram-positive, nonmotile rods and positive for nitrate reduction, lactose fermentation, and gelatin liquefaction. The use of TSC agar for enumeration and motility-nitrate medium together with lactose-gelatin medium for confirmation has been adopted as official first action by AOAC; however, the International Organization for Standardization and British Standard methods recommend the use of lactose-sulfite medium alone as a confirmatory test.[26,109]

In the UK in particular, the isolation of *C. perfringens* has been confirmed by streaking cultures on lactose–egg yolk medium to check for lecithinase activity.[104] This is seen as a zone of opalescence surrounding the colonies (Nagler reaction). Type A antitoxin is applied to half the plate to neutralize lecithinase produced by *C. perfringens*; occasional lecithinase-negative isolates would not be detected by this test.

A reversed CAMP test has been proposed for the presumptive identification of *C. perfringens*.[77] The procedure is based on the synergistic hemolysis (arrowhead-shaped) pattern produced on blood agar when *C. perfringens* is streaked at right angles to *Streptococcus agalactiae*. The procedure identified 97% of *C. perfringens* cultures tested with less than 1% false-negative reactions.[80]

A rapid (15 minutes) commercially available test (key iD strip) for presumptive isolated colonies is now available. Consisting of several paper-impregnated enzyme substrates, the test correctly identified all 73 *C. perfringens* strains tested and avoids the overnight incubation and requirement for type A antiserum.[25]

42.8.3 Serological Assays for Enterotoxin

The direct detection of CPE in outbreak stools is a useful technique for confirmation of *C. perfringens* as the etiological agent. Several serological assays for CPE have been developed including ELISA and RPLA, which have sensitivities of 2 to 4 ng g^{-1} feces.[16,123] Stools from healthy individuals contain undetectable levels of CPE[16] compared with outbreak stool samples, which contain >1μg g^{-1}.[13,16,17] A more recent ELISA method was described, with a detection limit of 1 pg ml^{-1} of purified CPE;[274] sensitivity in feces was not determined. A rapid ELISA (Tech Lab) and RPLA (Oxoid) are now commercially available. Instructions included with commercial CPE detection kit may be misleading by implying that a single sporulation medium will induce sporulation in all isolates whereas diarrheal strains often fail to sporulate *in vitro*.[119] An older serological assay method, counterimmunoelectrophoresis,[61,176] is used sometimes because of its simplicity although it is less sensitive.

Other serological methods for detecting CPE that have not been adopted widely include electroimmunodiffusion, reverse passive hemagglutination, fluorescent antibody, and single and double gel diffusion.[122]

42.8.4 Western Immunoblotting for Detection of Enterotoxin

Although ELISA and RPLA have proven very reliable, an occasional false-positive cannot be excluded.[13,190] In principle, Western immunoblots should provide a more specific CPE serologic assay because they can identify the 35-kDa CPE using antibodies prepared against purified CPE. The presumptive identification of a 48-kDa CPE-related protein as CPE[223] would also be avoided. Thus Western immunoblotting is the method of choice for verifying the enterotoxin-producing potential of clinical, food, and environmental isolates.[119] The drawbacks of the method remain the additional effort involved and the need to obtain at least low (up to 25%) levels of sporulation in cultures.

42.8.5 Gene Probe Methods for Detection of Enterotoxin-Producing (ent^+) Strains

Confirmation of the enterotoxin-producing ability of *C. perfringens* isolates by Western blotting or by serological methods depends on sporulation of the isolates. The difficulty of obtaining sporulation in laboratory media by this organism is well-known.[119,123] This led to development of methods for the direct detection of the *cpe* gene in vegetative cells of isolates. These detection assays include the use of PCR[228] and radioactive or digoxigenin (dig)-labelled gene probes.[9,119,268,277] Isolates identified as *cpe*-positive by such assays can only be regarded as potentially enterotoxigenic unless the ability of isolates to actually produce CPE is confirmed,[119] because it is not known whether isolates possessing the *cpe* gene also produce regulatory factors required for CPE expression.

Methods for detection of *C. perfringens* using a 16S rDNA-based PCR method[280] or 16S rRNA oligonucleotide probe method[217] have also been developed but do not specifically detect ent^+ strains.

42.8.6 Other Methods

Although tissue culture methods have been used previously to study the mode of action of CPE, the Vero cell line is also useful for assays of biological activity. Activity is measured as inhibition of plating efficiency[166,167] or killing of Vero cells.[146] Problems with reproducibility and nonspecific cytotoxic reactions were noted, however, when outbreak stools were used.[16] In the case of fecal samples, Vero cells were at least 10-fold less sensitive than ELISA or RPLA. The Vero cell assay is best used for mode of action studies or when biological activity of samples must be determined.

Many additional procedures have been used to study *C. perfringens*. These include bacteriocin typing,[281] plasmid profiling,[144,145,201] pyrolysis mass spectrometry,[238] immunomagnetic separation-ELISA,[43] dot-enzyme-linked immunosorbent assay (DOT-ELISA),[170] esterase electrophoretic polymorphism,[204] multilocus enzyme typing,[203] and impedance measurement.[250]

The sensitivity of *C. perfringens* to cold storage led to the development of methods to indicate previous growth of the organism in food. Lecithinase (alpha toxin) was proposed as an indicator because it is produced by the majority of strains.[83] To detect the enzyme in foods, a hemolysis indicator plate method was developed that requires at least 1.2×10^6 cfu g^{-1}

to have grown, although other workers found the minimum cell number to be about 10^4 cfu ml^{-1}.[58] The assay is dose-dependent above these thresholds. Other workers have found lecithinase activity to be time-, temperature-, and strain-dependent[180] and repressed in carbohydrate-supplemented media.[288] In addition, there have been occasional cases involving lecithinase-negative strains.[25,202] Thus the procedure is one of last resort, such as when patients' stools are unavailable or when the incriminated food has undergone prolonged cold storage. Nevertheless, the alpha toxin detection method has been adopted as official first action by AOAC for the examination of outbreak foods in which the presence of large numbers of vegetative cells are suspected but that may no longer be viable.

42.9 CONTROL

Unlike certain other agents of foodborne illness, it is not reasonable to expect *C. perfringens* to be absent from raw food products because the animal sources themselves harbor the organism. If present as spores, the organism can survive cooking, which effectively heat-activates the spores to promote germination when the product reaches a suitable temperature during cooling. The most practical way of preventing *C. perfringens* foodborne illness is by inhibiting the multiplication of the organism in food. Because the organism can multiply rapidly in protein foods, especially at 37° C to 45° C, food that has been cooked should either be kept above 60° C or cooled rapidly to below 7° C. Improper cooling after cooking has been identified as a principal cause of outbreaks in the US and UK.[27,211]

Cooking reduces the E_h of foods and thereby promotes anaerobic conditions; this is especially important in liquid foods and in rolled meats, where the contaminated outside surface is rolled into the middle. Other contributing factors that have been identified include inadequate hot holding and inadequate reheating of cooked, chilled foods. Reheating of cooked, chilled foods is important if the organism has had an opportunity to multiply because of previous temperature abuse. Such foods should be reheated to a minimal internal temperature of 75° C before serving to destroy vegetative cells. Certain public health agencies recommend holding cooked foods at or below 5° C (41° F) or above 60° C (140° F).[275] Such temperatures will effectively prevent the growth of *C. perfringens* in hazardous foods.

42.10 CONCLUDING REMARKS

Foodborne disease caused by *C. perfringens* continues to pose significant risk to human public health, especially in the aged or in individuals with underlying illnesses. Its widespread under-reporting impedes efforts at control and prevention. There must be greater awareness by public health agencies of its role in foodborne illness. The anaerobic conditions required to test outbreak foods for this organism are moderate in cost and effort.

The increasing demand and availability of minimally processed and *sous vide* foods present opportunities for growth of *C. perfringens* in products that have not been associated previously with it. This is particularly true given its broad temperature range and spore-forming ability.

Research efforts continue on determining the unique mode of action of the enterotoxin. As structure and/or function studies define specific epitopes of the toxin required for antigenicity, the possibility of a vaccine becomes possible. On another front, more rapid detection methods are needed that specifically identify ent^+ strains.

43.1 INTRODUCTION

The organism *Bacterium coli commune*, now known as *Escherichia coli*, was isolated by Escherich[123] from the stools of infants with enteritis. It was soon realized that *E. coli* was distributed widely in the intestines of healthy children and adults and other mammals. This commensal relationship, together with a lack of methods to differentiate *E. coli* strains, initially resulted in failure to recognize that some organisms had the potential to cause enteric disease. Differentiation of virulent and avirulent *E. coli* was achieved by the use of serological typing methods. These were first applied to study epidemic infantile enteritis[153] and subsequently developed by Kauffmann[208,209] to form a serological scheme that is the basis of the one used today. In the late 1940s, several *E. coli* strains associated with diarrheal disease were identified on the basis of their somatic O antigens,[43,147] and the division of the species into potentially pathogenic and commensal strains was established.

The importance of *E. coli* as a cause of diarrheal disease has been increasingly recognized over the past 25 years. Detailed comparison of the properties of diarrheagenic strains has resulted in the recognition of four categories of *E. coli* associated with disease. These are the enteropathogenic (EPEC), enterotoxigenic (ETEC), enteroinvasive (EIEC), and Vero cytotoxin-producing *E. coli* (VTEC). Other terms have been used to describe VTEC; these include Shiga-like toxin-producing *E. coli* (SLTEC) and more recently Shiga toxin-producing *E. coli* (STEC). The term enterohemorrhagic *E. coli* (EHEC) was introduced for those strains producing a bloody diarrhea;[228] therefore, EHEC are a subset of VTEC. EHEC possess virulence factors, in addition to Vero cytotoxin production, that are considered to be important in severe human disease. These properties are discussed in detail in Section 43.5.4. Strains of *E. coli* are identified as belonging to the above groups on the basis of their O and H (flagellar) antigens and the presence of specific virulence markers. There also may be features of clinical disease, epidemiology, and geographical distribution that are associated with particular categories. Further groups of *E. coli*, the enteroaggregative (EAggEC) and diffusely adherent strains (DAEC) have been linked epidemiologically in some studies with diarrhea.[121,329] Their virulence properties are defined less clearly than for the other groups, and the role of foodstuffs in their transmission is not established.

This chapter will consider the four major groups of *E. coli* that are associated with diarrheal disease in man. The newly emerging diarrheagenic groups will be included where information is available (Table 43–1).

Strains of *E. coli* have been associated with diarrheal disease in food-producing animals. These veterinary aspects have been comprehensively described recently.[165] Carriage of diarrheagenic *E. coli* by animals will be considered here only where there is evidence that strains harbored by animals pose a threat to human health either by contamination of food or by direct contact. In addition to diarrheal disease, strains of *E. coli* commonly cause urinary tract infections and a range of extra-intestinal diseases.[373] These infections are not foodborne and will not be considered here.

43.2 TAXONOMY AND TYPING

Castellani and Chalmers[54] first described the genus *Escherichia*, and the organism originally described by Escherich[123] became the type species *Escherichia coli*. The genus *Escherichia* is part of the tribe *Escherichiae* belonging to the family *Enterobacteriaceae* and contains five species. The other members of the genus are *E. hermanii*, *E. fergusonii*, and *E. vulneris*, all isolated from various human sources both intestinal and extra-intestinal, and *E. blattae*, only ever isolated from cockroaches. *E. coli* is the major species of the genus.

Escherichia coli are defined as oxidase-negative, Gram-negative rods ranging in size, 1-1.5 µm × 2-6 µm, usually motile by peritrichous flagella. They have an optimum growth temperature of 37° C but can grow over a wide temperature range from 15° C to 45° C. *E. coli* strains may also resist heating at temperatures of 55° C for 60 minutes and even 60° C for 15 minutes. Strains of *E. coli* grow well on most media forming smooth, circular, low convex colonies 2 to 3 mm in diameter.

E. coli are facultative anaerobes and ferment glucose with the production of acid and gas, although some strains are anaerogenic. The ability to ferment other carbohydrate sources is dependent on the conversion of relevant carbohydrate substrates to glucose or glucose derivatives. Lactose is fermented by most strains, but in some strains fermentation may be delayed or absent. Other carbohydrates usually fermented by *E. coli* include arabinose, glycerol, maltose, mannitol, rhamnose, and xylose. Fermentation of dulcitol, raffinose, salicin, and sucrose varies from strain to strain, and adonitol, cellobiose, and inositol are rarely fermented. Indole usually is produced and all strains are positive in the methyl red test and negative in the Voges-Proskauer test. Most strains do not hydrolyse urea or produce hydrogen sulphide in triple sugar iron (TSI) medium. Malonate is not used, phenylalanine is not deaminated, and gluconate not oxidized. Gelatin is not liquified, and almost all strains fail to grow in the presence of potassium cyanide (KCN). Most strains decarboxylate lysine and ornithine and are unable to use citrate as a sole carbon source (Simmon's citrate negative), whereas most strains of *E. coli* are able to use acetate as a sole carbon source. Strains also are capable of fermenting citrate in Christensen's medium, which is an important test to distinguish biochemically atypical *E. coli* from *Shigella*.[355]

As a result of the long association with disease, both in man and animals, many methods have been used to type and subdivide members of the *E. coli* species. These methods include colicin typing, biotyping, serotyping, phage typing, and, more recently, multilocus enzyme electrophoresis (MEE), pulsed field gel electrophoresis (PFGE), and restriction fragment length polymorphism (RFLP) analysis. Of all these methods, serotyping has been the most effective means of categorizing isolates of *E. coli* into

Table 43–1 Classes of Diarrheagenic *E. coli*

E. coli Class	*Toxins*	*Other Virulence Characteristics*	*Main O Serogroups*
Enteropathogenic (EPEC)	-	Bundle forming pili (BFP) Attaching and effacing lesions (intimin production)	55, 86, 111, 114, 119, 125, 126, 127, 128, 142, 158
Enterotoxigenic (ETEC)	Heat-stable, STI, STII, Heat-labile, LTI, LTII	Colonization factors associated with fimbriae or with the cell surface	6, 8, 15, 20, 25, 27, 63, 78, 128, 148, 153, 159, 167
Enteroinvasive (EIEC)	Enterotoxin (EIET) Cytotoxin	Invasion plasmid antigens (Ipa), 120 kDa outer membrane protein (VirG) necessary for cell-to-cell spread	28, 112, 124, 136, 143, 144, 152, 164, 167, 173
Vero cytotoxigenic (VTEC) or Shiga toxin-producing (STEC) (including enterohemorrhagic, EHEC)	Vero cytotoxins, VT1 and VT2 groups, Enterohaemolysin	Attaching and effacing lesions (intimin production)	5, 26, 91, 103, 111, 113, 128, 145, 157
Enteroaggregative (EAggEC)	Heat-stable, EAST 1, Heat-labile	Aggregative adherence fimbriae AAF/I, AAF/II	3, 44, 51, 77, 86, 92, 111, 126
Diffusely adherent (DAEC)	Not clearly defined	Adhesins, F1845, AIDA-I	1, 2, 21, 75

Note: The terms "pili" and "fimbriae" are used interchangeably.

closely related groups most frequently associated with particular virulence factors.

Serotyping is based on the identification of the following bacterial antigens. The somatic O antigens are composed of phospholipid-polysaccharide complexes. The specificity of an O antigen is determined by the terminal groups found in the repeating units of the polysaccharide chain. They are heat-stable (ST) antigens resistant to heating at 121° C. The capsular K antigen originally was used to describe the surface or capsular antigens that cause O inagglutinability. These acidic polysaccharide antigens originally were divided into three classes: A, B, and L. The A type K antigens are the most heat-stable, unaffected by heating to 100° C but their antigenicity is destroyed by heating at 121° C for 2½ hours. The existence of the B antigens has always been debatable, and Ørskov and others[281] recommended the withdrawal of this term for a K antigen. The L type antigens are heat-labile (LT) with their antigenicity destroyed by heating at 100° C for 1 hour. Only the A type K antigens are now considered to be important typing antigens, but they are associated mainly with pathogenic strains of *E. coli* from extraintestinal infections and not with those associated with diarrheal disease.

The flagellar H antigens are heat-labile protein antigens found in flagellin, the protein that constitutes the flagella found in motile *E. coli.* Strains usually are monophasic but rare diphasic strains have been reported.[299]

Kauffmann[208] devised a typing scheme incorporating all three types of antigen; he extended the scheme until, by 1947, it contained 20 O antigens, 55 K antigens, and 19 H antigens.[209] The scheme was adopted internationally and at present consists of O antigens, 1–173; K antigens, 1–103; and H antigens, 1–56. Currently, it is considered necessary only to determine the O and the H antigens to serotype strains of *E. coli* associated with diarrheal disease. The application of serotyping to isolates associated with diarrheal disease has shown clearly that distinct serogroups usually fall within the different classes of diarrheagenic *E. coli.*[127,238] The main O serogroups for each class are shown in Table 43–1. Some serogroups such as O111, O126, and O128 appear in more than one class. The use of bacteriophages for the epidemiological typing of *E. coli* strains was first promoted by Nicolle and colleagues.[274] Ahmed and others[7] developed a phage typing scheme for VTEC belonging to serogroup O157, and this scheme was later expanded.[214] The scheme uses 16 bacteriophages and now identifies 88 phage types (R. Khakhria, personal communication). In the United Kingdom (UK), the most common phage types found are 2, 21/28, 49, 1, 8, and 14,[2,303,386] whereas in Canada they are phage types 4, 8, 2, 1, and 31.[2,238]

43.3 CHARACTERISTICS OF THE DISEASE

Of all the *Enterobacteriaceae* found as part of the intestinal flora of man, *E. coli* is the predominant organism. *E. coli* are found in humans as part of the normal intestinal flora shortly after birth. Within a few hours, *E. coli* rapidly colonize the intestinal tract, becoming part of the normal flora within the large intestine. *E. coli* are ever present as part of the normal flora, a saprophytic commensal playing an important role in various physiological functions.[110]

43.3.1 Enteropathogenic *E. coli* (EPEC)

The disease caused by this group of *E. coli* is a watery diarrhea accompanied by vomiting and fever. The diarrhea is often self-limiting but EPEC can cause a protracted chronic enteritis leading to wasting and failure to thrive. EPEC are associated usually with infants and young children under the age of 3 years and are not routinely looked for in adults with diarrhea. EPEC were associated originally with large outbreaks of infantile enteritis in hospitals often with high mortality rates, but there have been few reports of outbreaks in the UK, Europe, or United States (US) since the mid 1970s. EPEC are still an important cause of diarrhea among children in the developing countries.[116,160,203,228]

43.3.2 Enteroinvasive *E. coli* (EIEC)

This group of *E. coli* produce a diarrhea that often clinically resembles bacillary diarrhea, the disease caused by *Shigellae.*[160,228,355] The diarrhea initially is acute and watery, accompanied by fever and abdominal cramps, progressing to the colonic phase where the stool becomes bloody and mucoid. Not all EIEC infections proceed to the colonic phase, so blood is not always detected in the stool. EIEC invade the colonic mucosa and multiply within the cells, spreading to adjacent cells after lysis of the infected cells. EIEC are biochemically atypical, often being anaerogenic, nonlactose fermenting, and lysine decarboxylase-negative, thus resembling *Shigellae.* Clinically, misidentification is not important but the accurate identification of the causative pathogen is epidemiologically important.

43.3.3 Enterotoxigenic *E. coli* (ETEC)

Disease caused by infection with ETEC is described as a watery diarrhea with abdominal cramps, fever, malaise, and vomiting. In its most severe form, infection with ETEC strains can produce a clinical picture resembling the diarrhea produced by *Vibrio cholerae*, that is "rice water stools." ETEC are a major cause of diarrhea in infants in the less-developed countries and also of travelers' diarrhea among those travelling from areas of temperate climate with good hygiene to areas, particularly in the tropics, with lower standards of hygiene.

43.3.4 Vero Cytotoxin-Producing (Shiga Toxin-Producing) *E. coli* (VTEC) (STEC)

VTEC were described first by Konowalchuk and colleagues in 1977,[220] but it was not until 1982 that they were recognized as significant causes of hemorrhagic colitis (HC) and hemolytic uremic syndrome (HUS).[207,309] Symptoms of HC often begin with abdominal pain and watery diarrhea, followed by bloody diarrhea usually without fever. The diarrhea, either bloody or nonbloody, may be followed by the development of HUS. This is characterized by microangiopathic hemolytic anemia and thrombocytopaenia, followed by acute renal failure. HUS occurs in all age groups but is most common in young children. The spectrum of disease caused by VTEC also includes thrombotic thrombocytopenic purpura (TTP).[206] With TTP, the clinical features of HUS are accompanied by fever and a low platelet count associated with formation of thrombi that give rise to severe neurological disorders.

43.3.5 Enteroaggregative and Diffusely Adherent *E. coli* (EAggEC and DAEC)

Enteroaggregative *E. coli* have been associated with persistent diarrhea in developing countries.[329] This diarrhea lasts for more than 14 days and usually is watery with vomiting, dehydration, and abdominal pain in some patients. Bloody diarrhea and fever have been described in children infected with EAggEC.[30,87] Diarrhea associated with diffusely adherent *E. coli* is characterized by mucus-containing watery stools with some fever and vomiting.[121]

43.4 EPIDEMIOLOGY OF *E. COLI* CAUSING DIARRHEAL DISEASE

There are significant differences in the incidence of outbreaks and sporadic cases of infection caused by the major groups of diarrheagenic *E. coli*. Changes in the epidemiology of infection due to some types of strains have been observed over the years. Different factors are of importance in developed countries compared with the developing world.

43.4.1 Epidemiology of EPEC

EPEC Infection in Developed Countries

Historically, these strains comprised the first group of *E. coli* for which epidemiological studies were carried out by applying a serotyping scheme. In contrast to the "summer diarrhea" that had been the annual scourge of infants in Europe and the US until the 1930s, outbreaks of infantile enteritis were observed with increasing frequency during the 1940s, principally during the winter. Investigation of nursery outbreaks in London and Aberdeen, Scotland, implicated *E. coli* of serogroups O55 and O111 as the causative agents.[43,147,366] Many epidemics of EPEC infection were reported in Europe and North America in the 1950s and continued in Britain until the early 1970s. Serotypes isolated from infected infants included O114:H2, O119:H6, O127:H6, O128:H2, and O142:H6.[160] An important feature of these outbreaks was a high attack rate accompanied by high mortality, which could exceed 50%. The highest rates of infection were in babies less than 6 months of age, particularly those that were bottle-fed.

Studies of outbreaks in Aberdeen and Dublin[147,192,366] indicated that infection was spread within the nursery after admission of infected infants from the community. Strains of EPEC excreted by infants caused widespread contamination of their physical environment and carers.[314] Transmission occurred by the fecal-oral route mediated by contaminated formula feeds and feeding equipment. Dissemination of EPEC on a global scale was indicated by retrospective studies of outbreaks in England, Scotland, Northern Ireland, Eire, Canada, Indonesia, and the US.[162] It appeared that a single EPEC clone of *E. coli* O142 was responsible for disease in all these countries.

Since the 1970s, there has been a marked change in the epidemiology of EPEC in developed countries. Outbreaks of infantile diarrhea have become rare in Britain and the US. This has been attributed to improvements in hospital hygiene, improved preparation and formulation of milk feeds, and better nursery management to avoid cross-infection. Sporadic cases of EPEC infection in children continue to be reported, with a peak in the summer months. There were 387 reports of diarrhea associated with EPEC in England and Wales in 1994 in children less than 3 years old (Communicable Disease Surveillance Centre, unpublished). There remains the potential for severe disease, exemplified by an outbreak caused by *E. coli* O114 in a daycare center in the US in which there was one death and secondary spread of infection.[41]

The contribution of EPEC to diarrheal disease in adults in the developed world is difficult to evaluate because most laboratories do not examine stools from patients over 3 years of age for these organisms. A few outbreaks have been reported, and in some of these a link with food or beverages has been established epidemiologically or by isolation of the organism from patients and from the incriminated food. In a waterborne outbreak in the US, *E. coli* O111 was isolated from stools and from well water that had been contaminated by sewage.[336] Multiple EPEC serogroups were isolated from a water supply that caused an outbreak in Sweden (quoted by Doyle & Padhye, 1989).[107] Outbreaks linked to food have been reported in Britain.[399] A large outbreak of diarrhea caused by *E. coli* O111 affected 650 children and adults in Finland and spread to 137 household contacts, but the source of the organism remained unknown.[401]

EPEC Infection in Developing Countries

In the developing world, or where standards of hygiene are poor, EPEC strains remain a major cause of diarrhea in infants. Outbreaks occur in institutions and the general community, together with sporadic infections.[85,116,154,203,229] The peak incidence of disease occurs in the warm season. Breastfeeding, which may continue longer in developing areas, provides a protective effect against infection.[349] Infants generally fall ill in the months following the start of weaning, probably because of fecal contamination of weaning foods by the water supply. Individuals may suffer several diarrheal episodes in the first three years of life.[85]

Studies on the epidemiology of EPEC have indicated that the reservoir of these strains is the gastrointestinal tract of man and that there is no evidence for zoonotic infections.

43.4.2 Epidemiology of ETEC

ETEC Infection in Developed Countries

Surveys of sporadic diarrhea in the US, Canada, Sweden, and Britain have indicated that ETEC are not an important cause of disease in developed countries in children or adults;[160] however, ETEC have caused outbreaks of infantile enteritis in hospitals in England, Scotland, and the US.[161,257,318,321] The epidemic strains isolated from these outbreaks included serogroups O6, O78, and O159. The sources and routes of transmission were unclear, although cross-infection was very important. In an outbreak that continued for nine months in the US,[321] there was extensive environmental contamination with the causative *E. coli* O78. The organism was recovered from milk feeds but not from unopened containers of formula. Contamination of food or water by ETEC may occasionally result in outbreaks of infection in the community. More than 200 staff and visitors at a US national park fell ill after contamination of the water supply with raw sewage. *E. coli* O6 was isolated from patients and drinking water.[315] Contaminated well water was associated with outbreaks in Japan.[223] Outbreaks of infection linked to foods have been reported in Japan,[223] England,[311] and the US.[55,240] Implicated vehicles of infection included contaminated turkey mayonnaise, imported French cheese, and salad vegetables. Individual food handlers with diarrhea have been implicated as the cause of some outbreaks.[381]

ETEC Infection in Developing Countries

Strains of ETEC are an important cause of diarrhea in all age groups in regions of poor hygiene, particularly in the tropics.[160] Rates of infection are highest in infants up to 2 years old and decline in older children and adults, indicating progressive development of immunity.[36,231] Infants may suffer two or three clinically significant episodes of diarrhea per year due to ETEC, particularly around the time of weaning.[33] Together with diarrhea of other etiology, this contributes to the development of clinical malnutrition, which in turn may reduce significantly the dose of ETEC required to cause diarrhea. Infections caused by ETEC reach a peak in the warm season. Infants are vulnerable to contaminated weaning foods but all may be exposed to water supplies contaminated by latrines or as a result of multiple uses.[34,36] Water stored in homes may become a source of ETEC that may also be transmitted on contaminated hands.[119] Studies in developing countries have shown that ETEC associated with human disease can be recovered from rectal swabs of healthy domesticated animals, including cattle and pigs.[36,120] This suggests that livestock may represent a further source of environmental contamination.

Travelers' Diarrhea

Travelers from temperate countries where standards of sanitation and hygiene are high are at risk of infection when visiting regions where ETEC are endemic. The relationship between ETEC and travelers' diarrhea was first demonstrated in studies of British troops arriving in southern Arabia.[320] Later studies on US and British military personnel deployed to Vietnam, the Philippines, Thailand, and the Arabian Gulf have supported this finding.[112,115,193,414] In Mexico, several investigations of travelers' diarrhea showed attack rates between 29% and 48%, with ETEC detected in about 50% of those ill.[113,155,251] In one Mexican study, consumption of salads containing raw vegetables was linked epidemiologically to infection.[251] This last study indicated that asymptomatic carriage of ETEC by travelers is uncommon.

In addition to the more obvious epidemic areas, travelers have acquired ETEC in Mediterranean countries. Surveys in Sweden and Britain revealed that 11% of travelers who developed diarrhea while abroad or shortly after return suffered from ETEC infection. There have been a number of incidents of ETEC infection on cruise ships, sometimes involving successive cruises by the same vessel. Hobbs et al.[186] reported the isolation of *E. coli* O27 from 55%, 61%, and 20% of diarrheal cases in three cruises by the same ship. These infections probably were foodborne. Microbiological and epidemiological evidence implicated the water supply on another ship as the source of infections, which were caused by ETEC of several different serogroups.[280]

43.4.3 Epidemiology of EIEC

Strains of EIEC were identified first in Allied troops suffering from dysentery in the Mediterranean during World War II.[128] The association of these organisms with an outbreak of disease was established when school children in Britain became infected with *E. coli* O124 after consumption of a midday meal.[187] Although the outbreak was thought to be foodborne, the organism was not isolated from a food item.

There have been several outbreaks of EIEC infection throughout the world. Settings have included hospitals and institutions in Britain, Australia, Czechoslovakia, and the US.[177,271,310,317,319] Both adults and children have been affected. Outbreaks of infection probably are foodborne, although the association usually has been epidemiological. However, in one investigation, a high level of *E. coli* O124 contamination of imported French cheese was linked directly with a large outbreak of infection in the US.[242] The source of contamination appeared to be improperly filtered river water used to clean the cheese-making equipment. Transmission of infection from person-to-person was identified during an outbreak of diarrhea associated with *E. coli* O124 in the US.[177,178]

Sporadic cases of EIEC infection appear to be rare in the developed world, although incidence may be underestimated because of the difficulty most clinical laboratories would have in identifying the organism. Like EPEC and ETEC strains, EIEC are endemic in many developing countries.[118,379] Children between 3 and 5 years of age are most at risk,[380] and the organism can cause travelers' diarrhea.[380,404] The reservoir of EIEC appears to be the gut of infected humans.[107] This conclusion has been based on the similarity of the organism to *Shigella* and a lack of evidence for animal carriage or for specific association with foods of animal origin.

43.4.4 Epidemiology of VTEC

In contrast to infections with EPEC, ETEC, and EIEC, diarrheal disease caused by VTEC has been recognized as an emerging problem, particularly in North America, Europe, and Japan. Surveys of nonselected diarrheal stools in North America and the UK indicated that between 0.1% and 2.7% contained O157 VTEC.[156,158,241,323] There have been few investigations of the incidence of VTEC other than O157, largely because of the lack of simple tests for the primary isolation of these organisms. Surveys of diarrheal stools in Canada,[283] Germany,[164] and Belgium[293] indicated that 0.7%, 6.6%, and 1% contained non-O157 VTEC, respectively; the corresponding findings for O157 VTEC were 2.5%, 2.7%, and 0.2%.

Several studies have established that O157 VTEC are a major cause of HC. In North America and the UK, these organisms have been isolated from between 15% and 70% of bloody stools.[156] Since Karmali et al.[207] first established the association between VTEC and HUS, many studies in North America and Europe[51] have shown that O157 VTEC are more commonly isolated from patients with HUS than are VTEC of other serogroups. Rates of isolation of O157 VTEC have ranged from 19% to more than 60% (summarized from Griffin and Tauxe[156]) although evaluation of the data is difficult because studies have varied in size and techniques used to identify VTEC strains. In England and Wales, HUS develops in about 10% of patients infected with O157 VTEC.[386] HUS has been recognized for many years as the most common cause of acute renal failure among infants and children in Argentina and Chile.[156,206] Evidence of VTEC infection in cases of HUS has been reported in Chile, Uruguay, and Argentina.[83,239] Currently, the annual incidence of HUS in children under 5 years of age in Argentina is 7.8 per 100,000,[423] with evidence of VTEC infection in about 70% of cases. O157 VTEC are most commonly associated with HUS patients with bloody or nonbloody diarrhea.

In a number of studies in Canada and the US, O157 VTEC strains were the second or third most frequently isolated enteropathogen and were more common than *Shigella.*[156] In Canada, the province of Alberta had the highest isolation rate of 15 per 100,000 population.[4] Strains of O157 VTEC are more frequently isolated in the northern and western US than in the South.[158]

The incidence of infections caused by O157 VTEC in England and Wales has been monitored by the Laboratory of Enteric Pathogens since 1983.[4,385,386] There has been a significant increase in the number of isolates of O157 VTEC and a rise in outbreaks caused by this organism in Britain.[352,360,402] For the period 1990 to 1996, the average annual isolation rate of O157 VTEC in England and Wales was less than 1.5 per 100,000, whereas in Scotland the average rate for this period was greater than 5 per 100,000. There is considerable geographical variation in the rates of isolation. In England for 1992 to 1996, the highest rates of O157 VTEC infection have been recorded by Northern, Trent, East Anglia, South West, and North West Health Authorities.[386] The lowest rates were in the Thames regions. Some of the variation seen in regional incidence in England and Wales may be the result of significant differences in ascertainment. In Scotland the highest rates between 1990 and 1994 were seen in Grampian and the Borders. Since then, rates of between 4 and 10 per 100,000 have been recorded in several Health Board areas, and in 1996 the Borders had a rate of 21.7 per 100,000 without any large reported outbreaks.[303] The increases probably result from improved isolation techniques and better ascertainment as well as a true increase in infections caused by O157 VTEC.

Surveillance of O157 VTEC infections in sporadic cases and outbreaks has shown that the age range of affected individuals in England and Wales is very wide—from less than 6 months to more than 80 years, with a peak in the 1 to 4 year age group.[385,386] Mortality rates are highest in young children and the elderly as seen in several outbreaks (Table 43–2). The organism is not an opportunistic pathogen and has caused fatal illness in previously healthy individuals. In contrast, investigations of contacts of patients has shown that some people can harbor O157 VTEC asymptomatically.[156,324] Studies in the US and Britain have shown a marked seasonality with peak incidence of infections in mid to late summer.[156,385,386]

Reported outbreaks of infection caused by VTEC have been predominantly associated with strains of serogroup O157. Table 43–2 lists examples of such outbreaks chosen to represent different countries, settings, food vehicles, and other modes of transmission. Community outbreaks have been recognized often by the appearance of a cluster of HUS cases; however, the proportion of patients within an outbreak who develop HUS is extremely variable[156] and is not a reliable outbreak marker. The first reported community outbreaks of infection with O157 VTEC occurred in the US in 1982 in Oregon and Michigan.[309] They were linked to consumption of ground beef sandwiches from the same restaurant chain, and O157 VTEC were isolated from frozen beef patties.[409] A very large outbreak (Table 43–2) occurred in the western US in 1993 and involved undercooked hamburgers from multiple outlets of a restaurant chain.[20,157] There was a significant number of secondary cases. Identification and withdrawal of the contaminated product were considered to have limited the scale of the outbreak. Although beefburgers from a restaurant chain were linked epidemiologically to O157 VTEC infection in Britain in 1991, the first isolation of O157 VTEC from a beefburger was associated with a small community outbreak in Wales.[421]

Some very large and serious outbreaks of O157 VTEC infection occurred in 1996. In Japan in 1996, more than 9,000 cases were reported in several different prefectures between the end of May and September with more than 5,000 people ill in Sakai City in July.[267,406,423] There were 16 outbreaks between May and November 1996,[252] in which school children were predominantly affected; it was suggested that school meals were the vehicle of infection but the specific sources were not identified. In Central Scotland, an outbreak occurred in November and December 1996, in which 501 cases were identified and 21 elderly people died.[8,291] The infections were associated with consumption of meat originating from a butcher and the O157 VTEC "outbreak"

Table 43–2 Examples of Outbreaks Caused by O157 VTEC Illustrating Possible Modes of Transmission

Year	*Location/Setting*	*Cases*	*Fatal*	*Transmission/Vehicle of Infection*	*Reference*
1982	Michigan, Oregon, US, Community	26		Hamburgers	309
1985	East Anglia, England, Community	49	1	? Handling raw vegetables	261
1985	Canada, Nursing home	73 (12 HUS)	17	? Sandwiches, person-to-person	52
1989	Missouri, US, Community	243 (2 HUS)	4	? Water	375
1990	Japan, Kindergarten	319	2	? Well water	222
1991	Preston, England, Fast food restaurant	23 (3 HUS)		? Beefburgers	385
1992/3	Western US, Fast food restaurants	732 (55 HUS)	4	Hamburgers	157
1992	Stockport, England, Hospital	14	3	Person-to-person	386
1993	Sheffield, England, Farm dairy/Community	7 (3 HUS)		Raw milk	69
1993	Gwent, Wales, Community	17 (1 HUS)		Butcher meat	421
1993	London, England, Community	7 (3 HUS)	1	Paddling pool/person-to-person	183
1994	Leicestershire, England, Visit to community farm	7 (4 HUS)		Animal contact	354
1994	Scotland, Community	100 (9 HUS)	1	Pasteurized milk	397
1996	Sakai City, Japan, Schools, Community	5,727 (>100 HUS)	3	? White radish sprouts	267,423
1996	Central Scotland, Community, Nursing home	501 (27 HUS)	21	Cooked meat, gravy	8, 291, 337, 338
1996	US, Canada, Community	66 (12 HUS)	1	Unpasteurized apple juice	57, 58

strain was isolated from gravy and also from a cooked beef joint.[337,338]

A range of food products of animal origin has been implicated or proven to be the vehicles of infection in outbreaks. In England, a small outbreak was caused by consumption of raw milk, and in Scotland at least 100 individuals became ill after drinking milk that became contaminated after pasteurization (Table 43–2). Some outbreaks have been linked epidemiologically to food vehicles such as sandwich fillings, cooked meats, and raw vegetables.[143,248,261,370] It is likely that the source of the organism in these cases was cross-contamination from raw meat or the exposure of raw vegetables to water contaminated with cattle feces. Occasional waterborne outbreaks of infection have been reported; one large incident in the US followed probable contamination of a municipal water supply after pipe fractures (Table 43–2).[375] The role of foods in VTEC infections will be discussed in Section 43.7.2.

Outbreaks of O157 VTEC infection in hospitals, nursing homes, and daycare centers have sometimes been associated with a high incidence of HUS and high mortality (Table 43–2).[52,385] In these institutional settings, person-to-person spread by the fecal-oral route has been of great significance after the initial cases. Assessment of the infectious dose of O157 VTEC from foodborne outbreaks has indicated that fewer than 100 organisms may cause disease.[4,421] Person-to-person spread is likely to be a factor in the large number of small family outbreaks of O157 VTEC infection that occur each year. A further mode of transmission of infection is by direct or indirect contact with animals, particularly cattle. In England, children and adults who visited a community farm became ill with O157 VTEC.[354] They had contact with cattle, goats, and other animals and had eaten a picnic meal without washing their hands. Identical O157 VTEC strains were recovered from patients, cattle, and goats. The role of animal carriage as a source of infection will be discussed later in this chapter.

Although some strains of VTEC other than O157 are human pathogens, they have been responsible for relatively few outbreaks of diarrhea or bloody diarrhea (Table 43–3). In Japan, a VTEC strain of serotype O145:H- caused an outbreak of diarrhea in a school,[199] and further Japanese outbreaks have involved strains of serotypes O111:H- and O104:H21.[222] Reports from Italy[50] and Australia[49,290] have described community outbreaks of HUS caused by VTEC of serogroup O111. In the Australian outbreak, there were over 200 cases; 22 children developed HUS and 1 died.[423] The source of the latter outbreak was traced to mettwurst, a fermented sausage. An outbreak in Montana resulted from contamination of pasteurized milk with VTEC of serotype O104:H21.[56]

43.4.5 Epidemiology of Newer *E. coli* Groups: EAggEC and DAEC

Studies on infants and children in developing countries have disagreed about the association between EAggEC and diarrhea. Gomes and colleagues[154] and Baqui et al.[16] did not find an association, whereas studies in India, Mexico, and Brazil have found a significant association of EAggEC with persistent diarrhea in children.[29,30,87,405] Strains of EAggEC have been isolated from travelers returning to Britain from abroad.[45,345] Cases of sporadic diarrhea in Britain have been linked to EAggEC, and the strains included a proportion that belonged to serotypes O44:H18, O111ab:H25, and O126:H27.[343,348] These three serotypes were recognized previously as EPEC serotypes based on epidemiological studies. Strains of serotype O44:H18 also have caused outbreaks of infection among young children and the elderly.[343,362] In 1994 several outbreaks of gastroenteritis in the UK were associated with EAggEC *E. coli* and contaminated foods were thought to be the source of the infections.[359] A preliminary study of infectious intestinal disease in England has indicated that EAggEC were found more frequently in cases than controls.[313]

Epidemiological studies of DAEC have been carried out in developing countries. Whereas some reports have found a significant association between these strains and diarrheal disease,[16,150,244] the majority of studies have failed to do so.[30,87,233] A more recent study indicated that the risk of infection with DAEC was greater in children between 4 and 5 years of age than in infants.[230] The incidence of DAEC in England is being studied as part of a study on infectious intestinal disease, but data are not yet available.

43.5 PATHOGENESIS MECHANISMS

43.5.1 Enteropathogenic *E. coli*

The adherence of EPEC to the intestinal mucosa, rather than toxin production, is the important mechanism in their pathogenesis. Polotsky et al.[295] observed histopathological lesions in rabbit ligated

Table 43–3 Examples of Outbreaks Caused by Non-0157 VTEC

Year	*Location/Setting*	*Cases*	*Fatal*	*Serotype*	*Transmission/Vehicle of Infection*	*Reference*
1984	Tokyo, Elementary school	100		0145:H–	Unknown	199

1995	Spain, School	13		0111:H–	? Drinking water	37

intestinal loops infected with classical EPEC strains, and similar lesions were seen also with intestinal biopsy material from infants with diarrhea.[316,396] This attaching and effacing (AE) lesion was characterized in detail by electron microscopy and shown to involve close attachment of the EPEC to the epithelial cells and destruction of the brush border.[218,259] Another advance in the study of EPEC pathogenesis came from the observation that "classical" EPEC isolated from outbreaks adhered to HEp-2 cells.[84] The bacteria formed clusters, later termed the localized pattern of attachment, whereas other types of *E. coli* and those from the normal flora rarely showed this adhesion. A plasmid, termed the EPEC adherence factor (EAF) plasmid, is necessary for the full expression of adhesion to HEp-2 cells.[13] Volunteer studies supported the role of this plasmid in EPEC pathogenesis.[232] Nine of ten subjects fed the wild-type EPEC strain had clinical diarrhea compared with only two of nine people receiving the plasmid-cured derivative. Chromosomal virulence factors are required in addition to the EAF plasmid.

Recent morphological and genetic studies have identified distinguishable stages of the adherence process.[411] The first step, resulting in localized adherence, is thought to be mediated by bundle-forming pili, the production of which is determined by the EAF plasmid.[149] There is then an alteration of the host cytoskeletal structure, including effacement of the surface microvilli, followed by the appearance of a pedestal-like structure on which the bacteria are localized. Intimate attachment to the epithelial cells requires a bacterial outer-membrane protein, termed intimin, encoded by the chromosomal *eae*A gene. Host cell responses following contact with EPEC include protein phosphorylation, increase in calcium levels, and rearrangement of cytoskeletal components under the adherent bacteria. The effect of these changes is that there is a significant reduction in the absorptive capacity of the brush border and a stimulation of intestinal secretion.

43.5.2 Enterotoxigenic *E. coli*

The pathogenesis of ETEC requires colonization of the small intestine and production of one or both of the two types of enterotoxin, LT and ST. The mechanisms of action of these toxins have been reviewed in detail.[263,350] Two types of LT enterotoxin are now recognized, designated LTI and LTII. LTI is related closely in its structure, function, and antigenicity to cholera toxin (CT) produced by strains of *V. cholerae*.[166,189] The structure comprises one polypeptide A subunit and five polypeptide B subunits, with molecular weights of approximately 30 kDa and 11.5 kDa respectively. The B subunits form a highly stable structure held together by hydrogen bonding and salt bridges. The A subunit is synthesized as a single polypeptide, but is split by proteolysis into a large enzymatically active peptide (A_1) and a small peptide (A_2) that connects the A subunit to the B pentamer. The A_1 and A_2 peptides are joined by a single disulphide bond that remains intact until the toxin enters a cell.

Each of the B subunits binds to the lactose-containing oligosaccharide portion of the monosialoganglioside GM1 in cell membranes.[159] Binding to the monosialoganglioside, GM2 and asialo GM1 has also been demonstrated.[190] Each B pentamer of LTI can bind five GM1 molecules; following this, the toxin is internalized. LTI and CT possess the same enzymatic function of adenosine-diphospho-ribosyl transferase activity in the A_1 fragment of the A subunit. Adenosine diphosphate (ADP)-ribose is transferred from nicotinamide adenine dinucleotide to a major specific target in the cell. This ADP-ribosylation occurs in the brush border membrane of the intestinal epithelial cell and results in activation of adenylate cyclase and a subsequent rise in the level of cyclic adenosine 5^1–monophosphate (cAMP). This stimulation of cAMP leads to electrolyte disturbances with increased secretion of chloride from crypt cells and impaired absorption of sodium and chloride by cells at the tips of the villi.[133,134] Water follows the electrolytes with a resultant profuse watery diarrhea.

LTI can be further subdivided into LTIh (human) and LTIp (porcine).[191] These toxins are closely related but can be distinguished immunologically: LTII differs from LTI in that it is not neutralized by antisera to CT or LTI. The structure of LTII is similar to that of LTI,[188] but LTII binds to the disialoganglioside receptors GD1a and GD1b and not GM1.[142] The enzymatic activity of LTII is the same as that of LTI, but production of LTII by *E. coli* is about 1% of the level of LTI. Like LTI, antigenic variation has also been observed with LTII, and subtypes LTIIa and LTIIb have been reported.[166] The properties of LTII have been characterized, but the role of this toxin in human disease has not yet been established. In contrast to the chromosomal CT genes, structural genes for LTI are located on plasmids and sequence analysis has shown >95% homology between LTIp and LTIh. There is approximately 70% homology between LTI and CT.[425] The structural genes for LTII are chromosomal, and the genes for the A subunits of LTIIa and LTIa have 57% nucleotide sequence similarity, but the B subunit genes for the two toxins lack significant homology.[292]

There are two major types of ST toxins: STI (or STa) and STII (or STb). These toxins are unrelated apart from their heat stability, secretion from the cell, and ability to cause diarrhea.[166] STI has a molecular weight of about 2000 and is resistant to 100° C for 15 minutes. The molecule is acid-resistant, susceptible to alkaline pH, and inactivated by reducing and oxidizing agents that disrupt disulphide bonds.[312] The STI toxins have been subdivided into STIa and STIb; they share antigenic determinants and biologically active sequences that are at the C-terminal end. The differences between STIa and STIb are at the N-terminal end, with identical central sequences of 11 amino acids.[371] STI binds to a specific receptor, reported to be a transmembrane guanylyl cyclase, located on brush borders of intestinal epithelial cells.[97,98,185] Binding of STI is maximal in villus preparations and decreases from villus to crypt.

The action of STI is to activate particulate guanylate cyclase in the brush border of the intestinal epithelial cells in the jejunum and ileum, leading to elevated levels of cyclic guanosine monophosphate (GMP).[132] The net effect is the inhibition of sodium-coupled chloride absorption in villus tips as well as stimulation of chloride secretion in crypt cells, leading to excessive fluid accumulation in the gut lumen.[136] The action of STI is very rapid but has a short duration. STI receptors are more widely distributed in the colon than in the ileum, and diarrhea caused by ST-producing *E. coli* represents the combined effects of fluid secretion in the small intestine and impaired absorption in the colon.

STII is a peptide comprising 48 amino acids but, unlike LT or STI, this toxin does not alter intracellular levels of either cAMP or cGMP. The mechanism of action is not known at present, although it has been proposed that STII acts by opening a receptor-operated calcium channel in the plasma membrane.[111] STII is produced by ETEC predominantly of porcine origin, usually in combination with other enterotoxins, particularly LTI.[53,166] STII, like STI, acts rapidly and for a moderate period with maximum fluid accumulation after 3 hours.

The genes for STI and STII are located on plasmids, and in the case of STIa and STII, the genes are carried on transposons.[226,369] DNA sequence analysis showed that STIa and STIb genes encoded products of 18 and 19 amino acids, respectively. STIa is synthesized as a 72 amino acid precursor that consists of a 19 amino acid signal peptide, a 35 amino acid pro sequence, and the 18 amino acid STIa. The DNA sequence for STII has also been reported: the structural gene encodes a mature protein of 48 amino acids and a signal peptide of 23 amino acids.[226]

Studies of enteritis in pigs first demonstrated that enterotoxin production was not sufficient to enable ETEC to cause diarrhea,[364] and this was shown later for strains of human origin. Adherence to the mucosal surface of the intestinal epithelial cells was the first essential step in ETEC pathogenesis. Most ETEC adhesins are nonflagellar, hair-like, rigid filamentous structures termed fimbriae or pili. ETEC fimbriae are host-specific and particular fimbriae are found exclusively on strains of either human, bovine, or porcine origin.[93,94]

Colonization factor antigen I (CFA/I) was the first adhesin on human ETEC to be characterized, and its role in disease was demonstrated in volunteer experiments.[125,126] CFA/I is a single antigen assembled into a rod-like fimbrial structure of 6–7 nm in diameter. In contrast, CFA/II comprises three antigenically distinct proteins—coli surface-associated antigens CS1, CS2, and CS3.[86,367] CS1 and CS2 are fimbrial antigens, while CS3 has a fibrillar structure; strains may produce CS1 and CS3, CS2 and CS3, or CS3 alone. CFA/IV comprises three antigenic components, CS4, CS5, and CS6. Several other colonization factors or putative colonization factors (PCF) produced by human ETEC have now been identified.[94,245,368]

Fimbriae are homopolymers composed of several hundred identical protein subunits, but in some cases there are minor proteins that are the actual adhesins. CFA/I fimbriae consist of a single type of subunit, of which only the tip-located subunit is accessible to the receptor.[47] The fimbrial adhesins of ETEC bind to glycoconjugates, glycoproteins, and glycolipids. This adhesin-receptor interaction occurs in a lectin-like fashion with the receptors located in mucus, epithelial membranes, and basement membranes.[93] The host specificity of ETEC results from the diversity of these glycoconjugates and their host distribution. Although most adhesins of ETEC have a fimbrial morphology, others such as CS6 are nonfimbrial. The adhesins in ETEC of human origin are usually encoded by plasmids.[368]

43.5.3 Enteroinvasive *E. coli*

Enteroinvasive *E. coli*, like *Shigella*, cause dysentery by invading intestinal epithelial cells. The invasion process includes several stages: entry of the bacteria into epithelial cells, intracellular growth, intracellular movement, and cell-to-cell spread. The result of these events is death of the host cell. The cellular and molecular basis of invasion and the genetic control have been reviewed.[172]

The entry of EIEC *E. coli* into mammalian cells requires energy production by bacteria and the host cell.[170,171] There is recognition of host-cell receptors, and entry is followed by reorganization of the cytoskeleton. This process requires transmembrane signal transduction. The genes required for entry are carried on a 220 kb plasmid, one region of which encodes several polypeptides termed invasion plasmid antigens.[328] These Ipa proteins are required for full invasiveness and are immunogenic.[169] Some of the antigens are necessary for adhesion before the entry step. EIEC *E. coli* can multiply intracellularly within a very short period after entry. An important factor is the ability of EIEC to lyse its phagocytic vacuole soon after entry, unlike other invasive pathogens such as *Salmonella* and *Yersinia*.[327] The organisms multiply freely in the cytoplasm of the epithelial cell. Rapid, random movements occur that allow cell-to-cell spread without entry into the extracellular medium. This property requires the 120 kD product of the *virG* gene located on the virulence plasmid.[227]

43.5.4 Vero Cytotoxin-Producing *E. coli*

There is a family of Vero cytotoxins, VT, also known as Shiga toxins (Stx) or Shiga-like toxins because they share many properties with Shiga toxin, produced by *Shigella dysenteriae* 1.[167,275,339] Two major types of VT (Stx), VT1 (Stx1) and VT2 (Stx2), have been described based on toxin neutralization and DNA hybridization tests.[342] VT1 is neutralized by antibodies to Shiga toxin but VT2 toxins are not. Variants of VT1 and VT2 have been reported, with most variation seen in the VT2 toxins. Strains of *E. coli* O157 often produce a variant—designated VT2c—together with VT2.[334,387] The VT2 variants are neutralized to some degree by antisera against members of the VT2 family, although titers are usually highest with the homologous toxin.[145,182] Several combinations of VT toxins have been observed in strains of different serogroups, and some VTEC of animal origin also produce enterotoxins (ST or LT).[361] Details of the different members of the Vero cytotoxin family have been summarized.[339]

Vero cytotoxins are LT proteins comprising one A subunit and five B subunits. Like Shiga toxin, VTs cause an irreversible inhibition of protein synthesis in eukaryotic cells. There is cleavage of the N-glycosidic bond at position 4324 in the 28S ribosomal RNA of the 60S ribosomal subunit. A single adenine residue is released and aminoacyl-tRNA no longer binds to ribosomes.[194] The A subunit of VT is converted into a large N-terminal A1 fragment that has the enzymatic activity of VT and a smaller C-terminal A2 fragment. The B subunits bind the toxin to the receptors present on cells in certain tissues. VT1, VT2, and Shiga toxin bind to the glycolipid Gb3 which has a Gal α1-4 Gal β1-4 Glc ceramide structure.[237] With the VT2 variants VT2c and VT2e, there is preferential binding to Gb4 [Gal NAc β-(1$\rightarrow$3) Gal α-(1$\rightarrow$4) Gal β-(1$\rightarrow$4) Glc ceramide].[326]

The distribution of receptors in different tissues, such as the kidney, probably accounts for the specificity of toxin targets.[307] The presence of Gb3 on different cell lines also correlates with the susceptibility of these cells to VTs. Erythrocytes also contain Gb3, and it has been suggested that the relative binding of VT may affect the development of HUS in certain individuals.[378] This has been supported by the observation that HUS patients had lower Gb3 levels on their erythrocytes than patients infected with VTEC who did not develop HUS.[272] The sensitivity to VT of human glomerular microvascular endothelial cells is related to their high Gb3 level.[279] VT is cytotoxic for these cells and several other primary cell lines.[277,278,383] The level of receptor expression by glomerular endothelial cells is increased by cytokines.[398] Production of cytokines by macrophages and monocytes can be induced by the action of VT.[382]

Animal models have been tested with VTEC or purified VT,[168] but it appears there is no satisfactory model for the human disease. Experiments with rabbits showed that VT was an enterotoxin as well as a cytotoxin because it caused fluid accumulation in ileal loops.[276] Intravenous injection of VT1 and VT2 in rabbits resulted in diarrhea, anorexia, and neurological symptoms but no changes were seen in the kidneys.[307] Use of radioactive labeling and immunofluorescence demonstrated binding of toxin to tissues and these sites had glycolipid receptors. The mouse model has shown that there are significant differences in the lethal doses for different types of VT. Pigs also have been investigated as a model by several workers, and neurological effects as well as brain and kidney lesions were observed after intravenous injection but there was no damage in the intestine.[144] Recently, a disease in dogs termed cutaneous and renal glomerular vasculopathy (CRGV) has been shown to have characteristically similar lesions to those seen in children with HUS.[179] Further work is needed to define the etiology of CRGV and to determine whether the greyhound is an appropriate animal model for VTEC infection.

The production of VT usually is encoded by bacteriophages in strains of *E. coli* O157, and VT phages have been detected in some strains of other serogroups;[308,344,365] however, the genes for VT2e production are chromosomal in strains of porcine origin. Therefore, cloning of the toxin genes was performed with phage DNA for VT1 and VT2,[273,419] but with genomic DNA for VT2e.[408] Sequence data have shown the relationship between the members of the family of VT toxins. The VT1 sequence shows only three nucleotide differences from the Shiga toxin gene, whereas VT1 and VT2 have 58% nucleotide homology. Within the VT2 and VT2 variant genes, there is at least 70% homology but there are significant differences between the A and B subunit genes.[339,363]

VTEC possess properties other than VT production that may be important in their pathogenesis. Like the classical enteropathogenic *E. coli*, some VTEC have the ability to attach to and efface the microvilli of the intestine. Strains belonging to serogroups such as O5, O26, 0111, and O157 possess this property.[173,284,393,395] In a recent review, Buchanan and Doyle[46] stated that "*E. coli* O157:H7 did not form attaching and effacing lesions . . ." when referring to work with calves more than 3 weeks old that had been infected experimentally. However, work by Dean-Nystrom et al.[96] clearly demonstrated AE lesions in neonatal calves. It was concluded from this latter study that O157 VTEC are pathogenic for neonatal calves, and the effects are age-related. The genes required for the formation of AE lesions are located on a "pathogenicity island" or LEE region (locus of enterocyte effacement) on the chromosome in O157 VTEC and classical EPEC strains.[247] However, there are differences between the *eae* genes of an O157 VTEC and an EPEC strain.[19,427] The two genes share 86% overall nucleotide homology but within the 800 base pairs at the C-terminal end, the homology is only 59%. The sequence differences in the *eae* gene have led to the development of probes that have been used to examine strains of *E. coli* O157 and VTEC of other serogroups.[417] The product of the *eae* gene, termed intimin, may have different binding specificities depending on whether it is produced by an EPEC or a VTEC strain. Experiments in piglets showed that an O157 VTEC strain with a mutant *eae* gene did not attach closely to colonic epithelial cells.[102]

VTEC belonging to certain serogroups lack the *eae* gene;[415,416] however, some of these *eae*-negative strains may possess adhesive properties.[92,341,416] Studies with strains of porcine origin showed that many *eae*-negative VTEC produced fimbriae, such as F107, that appear to be important in their pathogenesis.[195]

Another putative virulence factor of VTEC is enterohaemolysin (E-Hly) production.[27,28] E-Hly is produced by virtually all O157 VTEC and by strains belonging to several other serogroups.[25,416] The plasmid-located E-Hly gene in the *E. coli* O157 strain 933 demonstrated approximately 60% homology with the *hly*A genes and *hly*C genes within the α-hemolysin operon.[332,333] The function of E-Hly is unknown but α-hemolysin causes release of interleukin1ß; one effect of this cytokine is to stimulate the production of the glycolipid Gb3. Cells containing Gb3 are thus more sensitive to the action of Vero cytotoxins.

The properties of EHEC include the production of VT, the ability to form AE lesions, and production of enterohemolysin encoded by the large plasmid.[228] Not all VTEC possess the LEE region required for AE lesions or the large plasmid but may produce other factors involved in their pathogenicity; therefore, at present, it is preferable to use the term VTEC (or STEC) rather than EHEC.

43.5.5 Enteroaggregative and Diffusely Adherent *E. coli*

Use of adhesion tests with tissue culture cells led to the definition of aggregative and diffuse adherence.[121] Animal studies with rabbits, rats, and piglets have shown histopathological lesions in the small intestine caused by EAggEC. The villi become edematous with necrosis of the tips, and there is infiltration of leucocytes and erythrocytes.[394,400] Eslava et al.[124] reported similar lesions in the ileum of infants examined on autopsy following an outbreak caused by EAggEC. The aggregative pattern of adhesion also is seen with cultured human colonic mucosa.[219] Fimbriae or fibrils on the surface of EAggEC have been demonstrated and may be responsible for the adhesion.[121,219,264] The genes encoding bundle-forming fimbriae AAF/1 have been cloned with plasmid DNA from strain 17-2, serotype 03:H2.[266] A second fimbrial antigen of EAggEC termed AAF/II has now been defined.[121,265] Plasmid-encoded, surface-located proteins are produced by EAggEC of several serogroups; those of serotypes O126:H27 and O44:H18 are antigenically similar and proteins of 18kDa have been identified.[72]

The diarrhea caused by EAggEC may be partially secretory. Several toxins have been described but their role in disease has not been elucidated. The ST enterotoxin, EAST1, has been detected in a rabbit *in vitro* intestinal model.[330,331] EAST1 is functionally similar to the STI toxins of ETEC in that it increases intracellular cyclic GMP. An LT toxin with a molecular weight of 120 kDa also has been described; this induced rises in intracellular calcium and calcium-dependent phosphorylation.[15] This protein reacted with antibodies to hemolysin, but further work is required to demonstrate any role for this protein in the pathogenesis of EAggEC.

The pathogenesis of the diffusely adherent *E. coli* is poorly defined. The adhesion among DAEC is heterogeneous, and the genes encoding diffuse adherence may be plasmid or chromosomally encoded.[22,32] Adhesion of DAEC to human ileal and colonic mucosa has also been reported.[426] The DAEC strain C1845 induced inflammatory lesions in the ileum of gnotobiotic pigs.[32] Mild necrosis, villous atrophy, and inflammation associated with an infiltration of neutrophils into the mucosa was observed; changes were most prominent in the large intestine. A number of toxins, including α-hemolysin and cytolethal distending toxin, have been described in DAEC strains but none is clearly established in pathogenesis.

43.6 PRINCIPLES OF DETECTION

Recent advances in DNA-based and immunological techniques have led to improved diagnostic methods for the detection of pathogenic *E. coli*.

43.6.1 Enteropathogenic *E. coli*

EPEC have been detected for many years using a range of antisera prepared with strains of the traditional enteropathogenic serogroups; however, this approach will not detect strains with properties of EPEC that do not belong to these serogroups. In addition, many strains within the EPEC serogroups do not possess the characteristics of EPEC and belong to other groups such as the ETEC or the EAggEC. "Classical" EPEC show localized adhesion to tissue culture cells. Strains are tested for adhesion in the presence of D-mannose; the cells are washed after 3 hours and incubated for another 3 hours before washing, fixing, and staining.[340,347] The 6-hour test is recommended because shorter times have led to problems in distinguishing patterns of attachment. The ability to form AE lesions can be tested using the fluorescence actin-staining assay.[217] Adhesion of EPEC results in the accumulation of actin under the attached bacteria, and this can be visualized using fluorescein-labeled phalloidin, which binds tightly to actin. Areas of fluorescence indicate the presence of AE *E. coli* such as classic EPEC.

Alternatives to these tissue-culture tests have been developed. An antiserum to an EPEC strain, absorbed with a plasmid-free derivative, has been used in an enzyme-linked immunosorbent assay (ELISA).[9] This assay detected strains giving localized adhesion, whereas nonadhesive strains and other types of *E. coli* were negative. DNA probe and polymerase chain reaction (PCR) tests have been developed from sequences on the EAF plasmid of strain E2348/69 (serotype O127:H6). The first probe was termed the EAF probe[14] and more recently a probe has been prepared from sequences encoding the bundle-forming pilus (*bfp*).[148] Classical EPEC strains hybridize with both the EAF and *bfp* probes. A DNA probe and PCR primers have been developed from the *eae* gene, one of the genes necessary for the AE lesion.[201] This *eae* probe detects classical EPEC but also many other strains, including some Vero cytotoxin-producing *E. coli*, including O157 VTEC.

43.6.2 Enterotoxigenic *E. coli*

The enterotoxins of *E. coli* were first demonstrated in animal models, particularly with the rabbit ligated-ileal loop technique. Tissue culture methods then were developed for detection of the LT enterotoxins. Culture filtrates of LT-positive strains produce morphological changes in Y1 mouse adrenal cells and Chinese hamster ovary (CHO) cells;[103,163] Y1 cells become rounded, and CHO cells elongate on exposure to LT. Vero cells also are sensitive to LT. These tissue culture assays should be confirmed by neutralization with specific antisera. Several immunological techniques are available for detection of LT based on production of polyclonal or monoclonal antibodies to LT.[166] ELISAs use antibodies to LT or CT, or alternatively GM1 ganglioside, the receptor for LTI. Other tests include the reversed passive latex agglutination test, a staphylococcal coagglutination assay, and the Biken test, which relies on precipitin detection with cultures grown on a special agar medium.[357] Sequencing of the LTI genes has led to the design of polynucleotide and oligonucleotide probes and PCR primers.[424]

For several years, the most widely used method for the detection of ST enterotoxin STI was the infant mouse test in which culture supernatants are in-

Next Page

jected into the stomach of the mice.[95] The ratio of gut weight to remaining body weight provides the measure of fluid accumulation. Immunological assays proved difficult to develop because of the nonimmunogenic nature of ST. Antisera to purified or synthetic toxin can be produced after coupling the toxin to a carrier. A competitive ELISA based on synthetic toxin and use of a monoclonal antibody now is available commercially.[346] DNA probes and PCRs using the STIa and STIb sequences also have provided convenient tests of detection for STI-positive ETEC.[424]

43.6.3 Enteroinvasive *E. coli*

EIEC usually belong to particular serogroups, and antisera have been produced for detection of such strains; however, most of these serogroups are antigenically related to serogroups of *Shigella* and therefore EIEC may be mistakenly identified as *Shigella*. The tests for the invasiveness of EIEC will also detect *Shigella*. The invasive ability of EIEC first was shown in the Sereny test in which bacterial cultures are placed in the eye of a guinea pig and the eye is examined later for keratoconjunctivitis.[351] A tissue culture method, developed as an alternative to the animal test, uses HEp-2 or HeLa cells.[340] After an infection period, monolayers are washed and reincubated in the presence of antibiotics and lysozyme to remove extracellular bacteria. After staining and fixing, cells are examined for the presence of intracellular bacteria. Invasive bacteria can also be identified in an acridine-orange staining method in which counterstaining with crystal violet quenches the fluorescence of extracellular but not intracellular bacteria.[253] An ELISA for detection of EIEC has been described that uses a polyclonal antiserum prepared against an invasive strain and absorbed with a noninvasive derivative.[285] Results of the ELISA correlated perfectly with the Sereny test.

The invasive ability of EIEC is determined in part by a large plasmid and sequences from this plasmid have been used for DNA probes and as PCR primers.[17,141]

43.6.4 Vero Cytotoxin-Producing *E. coli*

Evidence of VTEC infection can be provided by the isolation of VTEC including *E. coli* O157, by demonstration of specific VT in fecal or food samples, or by the presence in serum of antibodies to *E. coli* O157 lipopolysaccharide.[61,73,357] O157 VTEC can be detected by plating fecal specimens on MacConkey agar with 1% D-sorbitol instead of lactose as, unlike about 95% of *E. coli*, O157 VTEC do not ferment sorbitol rapidly.[130] Sorbitol nonfermenting colonies are tested for agglutination with an O157 antiserum or with an O157 latex agglutination kit. Modifications of this method have led to significant improvements in selectivity, in particular due to the incorporation of cefixime and tellurite into sorbitol-MacConkey agar (CT-SMAC).[428] The use of an enrichment culture step before plating has resulted in higher detection rates for O157 VTEC from fecal samples.[184] Detection of O157 VTEC in food samples usually requires an enrichment step. Two liquid enrichment media have been widely employed; these are a modified trypticase soy broth containing novobiocin and buffered peptone water with added vancomycin, cefixime, and cefsulodin.[61] Immunomagnetic separation (IMS) for *E. coli* O157 also provides increased sensitivity of detection.[39,61,71,205] Incubation of the food sample in the enrichment broth for 6 h at 42° C followed by IMS and plating on a selective medium such as CT-SMAC (sorbitol-MacConkey) provides a satisfactory method that can detect O157 VTEC at a level of less than 1 to 7 organisms per gram of beefburger.[39]

For the enumeration of *E. coli* O157 in foods, direct plating on SMAC or derivatives of this medium is unsatisfactory because the numbers present usually are too low to detect. Most probable number analyses have been used for enumeration.[421] Direct surface swab tests with the 3M Petrifilm Test Kit–HEC without enrichment have been used to evaluate beef carcasses for the presence of *E. coli* O157.[48] Recovery of *E. coli* O157 was consistently higher with phenol red sorbitol agar containing methyl umbelliferyl glucuronide (MUG) or 1% pyruvic acid than with other media, including SMAC.[5] The incorporation of a resuscitation period on trypticase soy agar containing catalase gave improved recovery of heat-stressed organisms in a comparison with direct plating on SMAC containing MUG.[246]

Several commercially available kits have been developed for the detection of *E. coli* O157, with particular emphasis on the testing of foods. The EHEC-TEK kit, an enzyme immunoassay, has been compared with a noncommercial method.[63] The sensitivity of the EHEC-TEK kit can be one organism in 25 grams but the assay was improved by use of buffered peptone water supplemented with vancomycin, cefixime, and cefsulodin in place of modified *E. coli* broth containing novobiocin. The kit was simple to use, but did not appear to be as sensitive as IMS followed by culture on CT-SMAC agar. Several commercial test kits for the detection of *E. coli* O157 strains in minced beef have been evaluated.[181] The tests were the Ampcor *E. coli* O157:H7 kit, 3M Petrifilm test kit-HEC, Dynabeads anti-*E. coli* O157, EHEC-TEK, and the Tecra *E. coli* O157 visual immunoassay. A sensitive and cost-effective method was concluded to be enrichment in modified *E. coli* broth containing novobiocin for 6 to 8 hours, followed by IMS and plating on CT-SMAC.

VTEC belonging to serogroups other than O157 can be detected by testing for the production of VT or the presence of VT genes.[356,357] The standard method for VT detection is a cytotoxic effect on a monolayer of Vero cells. Cytotoxicity due to VT should be confirmed by neutralization using antisera against VT1 or VT2 or with both antisera. Recently, commercial tests for VT detection have become available and these include ELISAs (Vero Test Kit, Microcarb and the Premier EHEC Kit, Meridian) and a reversed passive latex agglutination test (Unipath). One of the enzyme immunoassays detected VTEC in ground beef and milk at levels of one organism per gram of beef or per milliliter of milk.[3] The method required overnight enrichment before the immunoassay. The presence of VT genes can be detected by DNA probes in hybridization experiments or by amplification in PCRs.[204,294,420] Oligonucleotide probes and PCR primers have been developed from each of the VT2 variant sequences reported to date.[363,424] A commercial PCR test for the detection of VT-producing *E. coli* O157 has been developed by Qualicon. Enriched food samples are examined for the presence of sequences unique to *E. coli* O157:H7. The method requires preparation of DNA and has a reported sensitivity of 10^5 colony forming units per ml. Full evaluations are required for the commercial tests for VT detection and also the PCR–based systems.

43.6.5 Enteroaggregative and Diffusely Adherent *E. coli*

Adhesion to HEp-2 remains the standard method for the identification of strains belonging to these two groups. Enteroaggregative *E. coli* show a stacked brick pattern of attachment, whereas DAEC adhere randomly over the cell surface. As for testing of EPEC, a 6-hour period for the adhesion is recommended. Isolates producing hemolysin are difficult to assay for adhesion as they may destroy the monolayer. Alternatives to tissue culture assays are being developed and used for testing *E. coli* isolated from fecal specimens. The EAggEC probe pCVD432 was prepared from the plasmid in strain 17-2.[18] This probe identifies a plasmid that encodes EASTI production and the adhesive property. The pCVD432 probe was not developed from the genes encoding AAF/I but has been highly specific for detection of some EAggEC.[121] Two probes have been reported for DAEC. The plasmid pSLM852 carries a fragment from the *daa*C gene of strain F1845;[32] this probe is specific but has shown low sensitivity indicating that there are several adhesins for the diffuse phenotype. The second DA probe, termed AIDA-1, detects sequences that appear to be rare among DAEC.[22,200]

43.7 ROLE OF FOOD, WATER, AND THE ENVIRONMENT AS SOURCES OF DIARRHEAGENIC *E. COLI*

43.7.1 Incidence of EPEC, EIEC, and ETEC

Data on the incidence of EPEC, EIEC, and ETEC in foods and the environment are very incomplete. Investigations usually have been linked to outbreaks in the developed world, although some household-based studies on ETEC have been carried out in endemic regions. It is rare for a suspected food vehicle to be available for microbiological examination, so many associations between sources and disease have been based on epidemiological data.

Symptomatic and asymptomatic human carriers are probably the most important source of EPEC, EIEC, and ETEC that cause disease in man. In regions of high incidence, there appears to be acquisition of immunity with age so that a pool of pathogenic *E. coli* is available by fecal shedding to infect the young. Contamination of food occurs from food handlers or from contact with water containing human sewage. Infection of adult healthy volunteers with these groups of organisms requires a dose of at least 10^8 organisms, which would be consistent with the amount ingestible through contaminated food or water. However, in developing countries factors such as lowered gastric acidity and malnutrition may result in infection with significantly lower doses. Strains of ETEC do not produce significant quantities of enterotoxins when present in foods under most conditions, and ingestion of preformed toxins is unlikely to be a health hazard.[107]

There have been few surveys on the incidence of EPEC or EIEC in foods. In the one microbiologically proven foodborne outbreak of EIEC infection, the levels of organism in the contaminated cheese were between 10^5 and 10^7 g^{-1}.[242] Foods in the US unlinked to outbreaks have been surveyed for ETEC. One study on cheeses failed to detect ETEC,[152] but they were detected in 8% of a range of foods including cheese, beefburgers, sausage, and seafood.[322] The majority of the strains belonged to serogroup O149, an ETEC group associated with pigs, although some human-pathogenic ETEC serogroups, such as O78, O15, and O25, also were found. ETEC also have been detected in cheese and yogurt in Germany.[140]

Studies on the incidence of ETEC in food and water in developing countries have been relatively unsuccessful in identifying specific sources of infection. These investigations have included sampling of different water sources in the environment and in homes of diarrheal patients and food from recently prepared meals.[36] About 3% of samples of domestic water used for drinking, cooking, or washing utensils were found to contain ETEC in the homes of patients with diarrhea in Bangladesh.[36] Studies in Thailand showed that only 3 of 588 food samples contained ETEC.[117] Levels of ETEC contamination in drinking water ($<10^2$ ml^{-1}) and food (10^2 to 10^3 ml^{-1}) were substantially lower than that estimated to cause diarrhea in volunteer studies. A later study in Bangkok identified ETEC in 3% of 510 market foods and from 13% of cases of diarrhea in children under 5 years of age.[298] However, the serogroups isolated from food and human sources were different. A study in Brazil identified ETEC as the second most commonly isolated group of diarrheagenic *E. coli* in a survey of raw ground beef.[60]

Food items usually considered to carry risk of travelers' diarrhea include untreated drinking water and foods exposed to such water and not cooked before consumption. It has been suggested that the lower incidence of ETEC-associated diarrhea in British troops in the Arabian Gulf compared with their US counterparts was due in part to differences in sources of food supply.[414] Virtually all food supplies for British troops were military rations shipped from Britain, whereas US troops were supplied from Egypt and Southern Arabia.

43.7.2 Incidence of VTEC

The contrast between the epidemiology of VTEC and other diarrheagenic *E. coli* has resulted in a much wider knowledge of their occurrence in the environment, animals, and food. Although asymptomatic carriage by humans has been observed, the principal reservoir for these organisms is the intestinal tract of cattle and sometimes other animals. Contamination of meat occurs when intestinal contents are spilled at slaughter, and milk may become contaminated with feces. The low infectious dose of O157 VTEC means that foods that are subject to cross-contamination from raw meat, untreated milk, or animal feces may in turn become vehicles of infection if not subsequently cooked.

Presence of VTEC in Cattle and Other Animals

Many serogroups of VTEC have been isolated from the feces of healthy cattle. VTEC have been isolated from between 10% and 17% of healthy cattle, and in most studies a proportion of the strains has belonged to serogroups associated with human disease.[258,413] Some strains, such as those of serogroups O5, O26, and O111, may be pathogenic for cattle causing severe bloody diarrhea.[173,353] These serogroups also have been associated with human disease.[416] Although O157 VTEC have been found in diarrheal calves, their role in disease was not established,[282,376] and it is generally accepted that healthy cattle may harbour VTEC, including O157 strains, with no ill effect.

Early studies to survey the carriage of O157 VTEC reported their presence in less than 1% of healthy adult cattle in Britain and Germany.[70,258] Similar results were reported in Washington state where O157 VTEC were found in 0.28% of dairy cattle and between 0.33% and 0.71% of beef animals.[174] In a study in the US of animals possibly linked to human disease, O157 VTEC were isolated from 2.8% of heifers and calves and 0.15% of adult animals.[410] Studies in England have demonstrated that animals within a herd may have several separate episodes of shedding of O157 VTEC during the year.[250] Changes in management practices, including diet, were associated with fecal shedding but there appeared to be no link with grazing potentially contaminated pasture. In contrast, a US study had tentatively identified fertilization with slurry and a short waiting period between application and grazing as risk factors for the presence of O157 VTEC in herds;[174] however, a recent study did not show a higher prevalence of O157 VTEC in herds in which heifers were grazed on pastures treated with manure.[175] In Canada, studies on persistence of O157 VTEC on dairy farms in Ontario showed that shedding appeared to be transient and *E. coli* O157 was not isolated from several farm environment sites.[296] A report of a study of farms in Wisconsin showed that 7.1% of the dairy herds were positive for O157 VTEC with isolations of the organisms from 10 of 560 calves.[129] In England, up to 3.6% of cattle tested at slaughter carried O157 VTEC.[67,68] Not only did carcasses of animals that carried O157 VTEC become contaminated with the organism, but it also was spread to carcasses of O157 VTEC-negative animals adjacent on the processing line.[68] Studies by Chapman and colleagues[65] have demonstrated that 15.6% of rectal swabs from 4,800 cattle contained O157 VTEC. Maule[2] has examined the survival of O157 VTEC using a laboratory-based model system. Survival was demonstrated in soil cores for 150 days and in cattle feces for 90 days, but was much reduced in cattle slurry (20 days) and river water (15 days).

Strains of O157 VTEC have been recovered in England from the feces of sheep passing through an abattoir; 2.2% of the 1,000 samples were positive.[65,66] Studies of O157 VTEC in a flock of sheep in the US showed that the incidence was transient and occurred during the summer.[224] Wild deer also have been shown to be colonized by O157 VTEC that may have been acquired from range cattle sharing the same habitat.[305] Farmed deer in Britain were reported to carry O157 VTEC.[62]

Outbreaks of O157 VTEC infection have been linked to farm visits[354] and sporadic infections have resulted from direct contact with farm animals.[289,391] The farm environment is likely to be contaminated with O157 VTEC from cattle but the organisms can also be harbored by sheep and goats, which increase the likelihood of spread. Fecal material on skin or fur may be transferred directly to humans who touch the animals or indirectly by dogs.[377,390] A survey in Ontario screened dairy cattle and families living on dairy farms for VTEC including O157.[76] All herds were positive for VTEC on the first visit but only 0.45% of animals from 5% of farms carried O157 VTEC. None of the humans tested was stated to have been ill, although 8% harbored VTEC including strains of serogroups O5, O91, O103, and O157. In the working environment, transient carriage of VTEC occurred in clinically normal cattle and humans.

Although pigs carry VTEC, the serogroups identified rarely have been found in cases of human infection. A range of VTEC, but not O157, was harbored by healthy domesticated animals including cats and dogs, thus providing a further means of environmental spread.[26] There is no evidence that poultry are a natural source of VTEC including *E. coli* O157;[65] however, chicks became colonized with O157 VTEC after laboratory inoculation; they shed the organism for up to 11 months in their feces, and the shells of their eggs became contaminated.[335]

VTEC in Meat

Strains of VTEC have been recovered from between 9% and 25% of beef and beef products including sausages, beefburgers, and ground beef;[302,358,418] however, the serogroups identified did not include O157 VTEC. In a study examining a wider range of retail food samples (meat, poultry, and seafood), 17% of the samples were positive for non-O157 VTEC.[325] In contrast, Doyle and Schoeni[109] reported that O157 VTEC were present in 1.5% to 3.7% of samples of retail beef, pork, lamb, and poultry in North America. Part of their study was carried out in an area with a high incidence of O157 VTEC infection, and the possibility of cross-contamination before sale could not be excluded. A large study summarized by Griffin and Tauxe[156] reported O157 VTEC in 0.12% of raw beef samples.

Recent studies in Britain detected O157 VTEC in 5.9% of retail lamb products; the highest incidence, 7.2%, was in lambburgers.[64] In the same study, O157 VTEC strains were detected in 2.1% of retail beef products. A survey of raw meats in the Netherlands, using PCR, showed the presence of VT genes in 16.1% of samples of minced mixed beef and pork and minced beef samples.[180] None of the VTEC isolated from the PCR-positive samples belonged to serogroup O157. In the same report, only 2 of 770 meat samples were positive for O157 VTEC after testing by selective enrichment in mTSB with acriflavin, followed by plating on SMAC agar. VTEC but not strains of O157 were recovered from 20 of 105 samples of raw ground beef in Rio de Janeiro.[60] In this study, VTEC were the most commonly isolated group of diarrheagenic *E. coli*. A survey of red meat, poultry, and pork products in Argentina in 1996 isolated O157 VTEC from 0.4% of beef samples but not from beefburgers.[423]

Several isolations of O157 and other VTEC from foods have been the result of investigation of outbreaks or sporadic cases of disease. O157 VTEC were isolated in the US from hamburger patties in the first documented outbreak of HC[309] and from a batch of ground beef used to prepare burgers associated with a much larger outbreak.[20,157] In the latter investigation and in a report of O157 VTEC isolation in Britain,[421] attempts were made to quantify the number of organisms present in the meat samples. Most probable number analyses indicated a level of between 1 and 15 organisms per gram of uncooked beef. Keene et al.[213] reported an outbreak of O157 VTEC infection in the US that was traced to jerky, which was made from the drying of deer meat.

VTEC in Milk and Dairy Products

The importance of unpasteurized milk as a vehicle for infection was recognized in outbreaks in North America,[210,270] England,[69] and the Czech Republic.[31] A large survey failed to detect O157 VTEC in milk, dairy, and associated samples in the UK but the efficiency of the detection methods was recognized to be poor.[268] A more recent study in the US failed to detect O157 VTEC in soft and semi-soft cheeses, in the dairy environment, or in raw milk.[10] The largest milkborne outbreak to date was in 1994 in Scotland and involved heat-treated milk from a local dairy.[397] O157 VTEC indistinguishable from the human isolates were obtained from a pipe carrying milk from the pasteurization apparatus to the bottling machinery and from a discarded bottle machine rubber. Cheese prepared from raw cow's milk was the vehicle of an outbreak of O157 VTEC infection in Scotland[352] and in Northwest England in 1997.[80]

Strains of VTEC other than O157 have been associated with sporadic cases or outbreaks of infection. VTEC of serotype O22:H8 were identified in Germany in a patient with HUS and in milk from the patient's home and the supplying dairy.[38] An outbreak of gastroenteritis and bloody diarrhea in Montana was attributed to a VT2-producing strain of *E. coli* O104:H21.[56] There was a strong epidemiological link with consumption of one brand of pasteurized milk, but the implicated organism could not be cultured from samples obtained at the dairy or from rectal swabs taken from cattle on farms supplying the raw milk.

Incidence of VTEC in Other Foods

The range of food items implicated in outbreak and sporadic cases of VTEC infection has widened in recent years. In some instances, foods or beverages have been prepared from contaminated ingredients and organisms have not been inactivated in subsequent treatment. In 1994, dry cured salami was implicated as the source of O157 VTEC in an outbreak in the US.[388] At a similar time, mettwurst sausage contaminated with O111 VTEC caused an outbreak in Australia.[49,290,423] In these incidents, the survival of the VTEC strains during the fermentation and drying processes (see Section 43.8.2) provided a warning that the preparation of manufactured foods previously thought of as safe may have to be reconsidered. Identification of O111 VTEC in foods and in patients' stools posed particular difficulty in the Australian outbreak: unlike the use of sorbitol MacConkey agar for O157 VTEC, there are no simple tests for the rapid discrimination of O111 VTEC. An outbreak of O157 VTEC infection in the US was linked to consumption of apple cider, the unfermented juice of windfall apples.[23] This drink, because of its acidity, was not considered particularly hazardous and was drunk unpasteurized. It appeared that the apples were contaminated with cow manure in the orchard. Other outbreaks of O157 VTEC infection caused by drinking unpasteurized commercial apple juice occurred in the US and Canada in late 1996[57] and in Connecticut in October 1996.[58] In one of the outbreaks, O157 VTEC was isolated from an unopened container of the apple juice.[57] In June and July 1997 outbreaks of O157 VTEC infection occurred in Michigan and Virginia. Both instances were associated with eating alfalfa sprouts grown from the same seed lot.[59] In the very large outbreak in Sakai City, Japan, in 1996,[252,267] white radish sprouts were considered the most likely vehicle but this was not demonstrated microbiologically. In 1997 *E. coli* O157 was detected in white radish sprouts associated with sporadic infections.[423]

Many of the food vehicles implicated as sources of VTEC infection may have become cross-contaminated during preparation in the home or in catering establishments. Raw meat, meat products, or juices may contaminate other foods directly or via surfaces, utensils, knives, and hands to provide the low dose that may lead to infection. Foods possibly contaminated in these ways include salads, vegetables, fruit, mayonnaise, cooked meats, and sandwich fillings. Several institutional and community outbreaks have been linked epidemiologically to the last two items. Even when there has been no known contact with meat or milk, cases of O157 VTEC infection have been noted. One incident involved a strict vegetarian who fell ill after consuming garden vegetables that had been fertilized with O157 VTEC-containing manure from the family cow.[74]

Association of VTEC with Water

There have been sporadic cases and outbreaks of infection with O157 VTEC linked to consumption of water or its use for recreational purposes. Although epidemiological investigations may have indicated water as the vehicle of infection, microbiological confirmation usually has been lacking. Reasons for this may include insensitive detection methods and the likelihood that by the time water was suspected as a vehicle, it was too late to obtain samples relevant to the time of infection. There appears to be very little information on non-O157 VTEC in relation to water, and methods to optimize the isolation of these organisms require further development.

Laboratory studies summarized in the next section have shown that O157 VTEC can survive in untreated water. Infection has probably resulted from consumption of water from streams[269] or dams[197] that have been contaminated by cattle. Accidental ingestion of untreated water appears to have caused a sporadic case of infection in an individual who fell into a lake from a houseboat[269] and an outbreak among bathers swimming in a lake in Oregon.[212] Relatively small quantities of water probably were swallowed in these incidents, providing further evidence of the low dose of O157 VTEC needed for infection.

A survey of risk factors associated with O157 VTEC infection in Scotland indicated that 12% of cases had access to a private supply of drinking water. This study also showed that failure in the supply of potable water was a risk factor in 12% of cases.[79] Well water was suspected as the vehicle of infection in a large outbreak in Japan,[222] and water from little-used reservoirs may have caused a small community outbreak of O157 VTEC infection in Scotland.[99] In these cases the origins of the O157 VTEC were not identified, although in rural areas contamination of water supplies with cattle feces is likely. Contamination of the mains' water supply was implicated in a large outbreak of O157 VTEC infection in Cabool, Missouri (Table 43–2). The town received its water from a nondisinfected groundwater source. Two large water mains fractured in very cold weather and backflow of sewage may have occurred. Contamination of the public water supply was concluded to be the source of an outbreak of O157 VTEC and also of campylobacter infection in Scotland.[202]

Paddling pools may be associated with O157 VTEC infection in young children. In one incident in Scotland, a domestic pool filled from a main's water was probably fecally contaminated with O157 VTEC by one of the children.[44] A second outbreak involved a municipal pool in London at which disinfection procedures were inadequate.[183]

Occurrence of VTEC in the Environment

From the above discussion, there appears to be circumstantial evidence that surface waters may become fecally contaminated by VTEC including O157 from animals. There have been few studies, however, to examine environmental samples prospectively. One study in the Philadelphia area examined water samples from 15 environmental sites, including streams and reservoirs.[249] O157 VTEC was detected only in one sample, from a reservoir 45 km from the city; the origin of the bacteria was thought to be deer.

43.8 FACTORS AFFECTING SURVIVAL AND GROWTH OF DIARRHEAGENIC *E. COLI* IN FOODS

43.8.1 Diarrheagenic *E. coli* Other Than VTEC

Most studies on the survival and growth of pathogenic *E. coli* associated with diarrhea were performed in the late 1970s and early 1980s. They did not examine specific groups of *E. coli* and generally used various mixtures comprising ETEC, EPEC, and EIEC strains so that detailed information on the effect of environmental parameters is not available for each group. Some strains have been re-examined more recently for comparative purposes as part of studies on survival of VTEC, principally O157 strains. No studies have been published on the aggregatively adherent and diffusely adherent groups of *E. coli*.

The effect of concentration of sodium chloride (NaCl) and sodium nitrite, pH, and temperature on growth of a 10-strain mixture of EPEC, ETEC, and EIEC was studied in brain-heart infusion broth.[146] Levels of NaCl of 8% (w/v) or higher inhibited growth irrespective of other factors. In 6% NaCl, growth occurred between pH 6.8 and 5.6 at temperatures in the range of 15° C to 35° C but not at 10° C. At pH 6.8 or 6.2, the strain mix grew in any combination of sodium nitrite (0 to 400 mg ml^{-1}) and NaCl (0% to 4%) at temperatures between 15° C and 35° C. Overall, the *E. coli* mixture showed better survival than a cocktail of *Salmonella* strains, although it was impossible to determine whether the different *E. coli* pathogens were behaving similarly.

A recent study on O157 VTEC used strains of EPEC and EIEC for comparison in tests of acid tolerance.[11] When 10^4 cfu ml^{-1} of an EPEC strain of serotype O127:H6 were inoculated into artificial gastric fluid pH 1.5, there was 26% survival after 1 hour, a similar result to that obtained with some O157 VTEC (see Section 43.8.2) (data recalculated from Arnold and Kaspar[11] as actual percentage of survivors). Other EPEC and EIEC were undetectable in 2 hours or less, and a nonpathogenic strain survived for only 30 minutes. In the presence of food, the pH of the stomach contents probably would exceed 1.5, increasing the likelihood that EPEC and EIEC strains would survive to enter the small intestine.

Outbreaks of infection with diarrheagenic *E. coli* in which cheese was implicated as the vehicle of infection resulted in several studies of survival of strains during fermentation of dairy products and cheese making. In a model system,[137] a mixed inoculum of ETEC and EIEC strains grew by 1 to 3 $\log_{10}$ units in skim milk at 21° C and 32° C in the presence of different levels of lactic starter culture. However, growth of the *E. coli* strains was inhibited completely after 6 to 9 h by the lactic acid bacteria. Strains of *E. coli* O124, O125, and O128 grew during preparation of Camembert cheese from pasteurized milk inoculated with 10^2 cells ml^{-1},[288] but then declined as the pH of the products fell to 5.0 or below. After storage at 10° C, viable cells were undetectable after periods up to 9 weeks. Survival of pathogenic *E. coli* was better in cheese made by a modified process that resulted in a product with better buffering capacity that did not reach such a low pH.[297] Strains of *E. coli* could grow within the mycelial mat of *Penicillium camembertii* during cheese ripening at 10° C, indicating that cross-contamination of cheese surfaces could result in a product potentially hazardous to the consumer.[138] Studies on the preparation of hard cheese from artificially contaminated milk showed that strains of ETEC or EIEC multiplied by 2 to 3 $\log_{10}$ units during the manufacturing process, then declined gradually during ripening and storage but were still detectable after 4 to 7 weeks.[139,221]

43.8.2 VTEC

It is clear from the previous sections that VTEC, including strains of serogroup O157, may be present on raw foods. These include products of animal origin such as meat and milk and a range of other foods that may become cross-contaminated with VTEC. The low infectious dose of O157 VTEC implies that growth of the organism in food may not be a prerequisite for disease. The majority of data on survival and growth of VTEC relate specifically to *E. coli* O157:H7. The effects of temperature, pH, NaCl concentration, and carbon dioxide on growth, survival, and thermal inactivation have been studied, and a predictive model is available.[135]

In laboratory media such as trypticase soy broth, O157 VTEC multiplied rapidly between 30° C and 42° C with an optimum of 37° C.[108] Growth was poor at 44° C to 45° C and did not occur within 48 hours at 10° C or 45.5° C. The maximum and minimum temperatures for growth in brain heart infusion broth were obtained for 23 O157 VTEC isolates from different sources and 3 VTEC of other serogroups.[286] All strains grew at 10° C and a few at 8° C although the time to achieve a 1,000-fold increase in viable count ranged from 6 to 46 days. Growth has been observed between 6.5° C and 7.2° C in laboratory media when the conditions are favorable;[4] O157 VTEC may survive, in the absence of growth, at such temperatures in laboratory media (eg, trypticase soy broth) for 15 days at 5° C.[176] There appears to be some strain-to-strain variation in the maximum growth temperature but incubation temperatures in the 44° C to 45.5° C range, such as may be used for the detection of fecal coliforms in food, are unsatisfactory for the recovery of O157 VTEC.[106] Some VTEC, such as *E. coli* O26, may also be inhibited by high temperatures.[286]

Strains of O157 VTEC survive well in foods during freezing and frozen storage. In beef patties frozen at –80° C and stored at –20° C, there was little change in numbers of O157 VTEC after 9 months,[108] and 50% survival was reported in ground chicken meat stored at—20° C for 18 months.[82] Raw milk inoculated with O157 VTEC (10^1 to 10^3 cfu ml^{-1}) and frozen at –20° C yielded the organism after 63 days of storage.[10] The long-term survival of pathogens in frozen foods means that tracing the sources of contaminated raw materials may be virtually impossible. The conditions of freezing and thawing affect the degree to which microorganisms become injured and die, which may explain the relatively poor viability of O157 VTEC in one study in which only 9 of 23 previously positive samples were viable after 1 year's frozen storage.[255] Additives such as NaCl and sodium lactate decreased survival of O157 VTEC during freezing but did not result in their elimination after 18 months.[82]

Growth of O157 VTEC in foods at chilled temperatures has been reported. These included lettuce and cucumber at 12° C[1] and apple cider at 8° C.[430] Although numbers declined, O157 VTEC survived on lettuce at 4° C for up to 14 days,[1] and packaging of salad vegetables under a modified atmosphere (3% oxygen, 97% nitrogen) had little or no effect on the survival or growth of O157 VTEC at 4° C, 12° C, or 21° C. Under conditions that do not permit growth, O157 VTEC may survive refrigerated conditions for a time period long enough to be hazardous to the consumer. Strains of O157 VTEC inoculated at 10^3

cfu ml^{-1} did not grow at 5° C in milk or ground beef but remained viable.[287] There was growth at 8° C in milk or beef in which the background flora was low ($<10^3$ cfu ml^{-1}), but high background (10^5 cfu ml^{-1}) inhibited growth although the O157 VTEC survived. Consistent with these observations, growth of O157 VTEC at 8° C or 15° C was slower in raw milk than in pasteurized milk.[403] Pasteurized milk supported higher levels of O157 VTEC and viability was retained for longer than in raw milk. Milk that is contaminated after pasteurization and subjected to mild temperature abuse may contain O157 VTEC in sufficient numbers to cause infection. At 8° C, spoilage of pasteurized milk in the above tests was not detected after 28 days even though O157 VTEC was present at approximately 10^6 cfu ml^{-1}.

Several studies have demonstrated that O157 VTEC have no unusual resistance to heat. Doyle and Schoeni[108] reported *D* values at 62.8° C of 24 seconds and 42 seconds, respectively, for O157 VTEC and a strain of salmonella in ground beef. In pork and chicken homogenate, the *D* value at 64° C was 0.46 minutes.[24] The heat resistance of O157 VTEC was greater in fatty than lean ground beef.[236] The effect of product composition on the thermal death of O157 VTEC was demonstrated in ground beef, pork sausage, chicken, and turkey containing fat levels up to 30%.[6] The *D* values in the lowest fat products were lower than those in traditional beef and pork items. In milk, O157 VTEC strains are eliminated by pasteurization. In a study of thermal inactivation of pathogens in milk, exposure to 72° C for 16.2 seconds killed more than 10^4 O157 VTEC ml^{-1}.[89] At subpasteurization temperatures, O157 VTEC were more resistant to heat than *Yersinia enterocolitica* or *Campylobacter* species. Although O157 VTEC grew during the manufacture of cottage cheese, the bacteria were killed when the curd was cooked at 57° C for 90 minutes.[12]

Conditions for growth and growth phase affect heat resistance of O157 VTEC. Strains of VTEC were more resistant to heat when in the stationary phase.[389] Anaerobic growth resulted in *D* values at 55° C that were higher than for aerobically grown organisms.[262] The packaging of raw meat and vegetables under modified atmospheres could result in increased heat resistance of contaminating O157 VTEC. Brief exposure of O157 VTEC to elevated temperatures (42° C for 5 minutes) increased the *D* value at 55° C by a factor of 1.5 to 2.1.[262] It was speculated that mild heat shock that might occur during mishandling of food could compromise the ability of subsequent heat treatment to render the product safe. O157 VTEC may be more resistant to heat in sugar solutions rather than in salt at the same water activity.[135]

There are few data on the effect of water activity on the growth of VTEC. O157 VTEC grew in trypticase soy broth with salt concentrations up to 6.5% w/v corresponding to a water activity of 0.97.[151] Growth was inhibited at NaCl concentrations in excess of 8.5% w/v. Growth medium and temperature affect salt tolerance of O157 VTEC. Thus at 37° C, growth of O157 VTEC was inhibited at 8% NaCl but at 10° C there was inhibition at 4% to 6% NaCl.[81] It was concluded that the salt tolerance of O157 VTEC was similar to that of other *E. coli* serotypes and might be greater than that of *Salmonella* and *Campylobacter.*

Several outbreak investigations indicated that O157 VTEC infections had been associated with consumption of acidic foods that generally had been regarded as a low risk. Some of these were described in Section 43.4 and included live yogurt,[260] apple cider,[23,57] and mayonnaise.[211] These findings led to detailed study of the acid tolerance of O157 and some other VTEC in laboratory media and food. In Luria broth acidified with HCl to pH 2.5 or 3.0, there was no loss in viability of one O157 VTEC strain incubated at 37° C for 5 hours.[21] Five other O157 VTEC and several VTEC strains of serogroups O15, O22, O26, O111, and O165 were also acid tolerant but to a lesser extent. After 2 hours at 37° C, the percentage of bacteria remaining viable at pH 3.0 ranged from 26% to 80% and at pH 2.5 from less than 1 to 72%. In artificial gastric fluid at pH 1.5, most O157 VTEC survived for at least 1 hour.[11] For four strains, between 14% and 26% of the initial inoculum (10^4 cfu ml^{-1}) remained viable at the end of this period (recalculated from Arnold and Kaspar[11] as actual percent of survivors) and they were still detectable after 3 hours. A nonpathogenic *E. coli* control strain could not be recovered after 30 minutes. These results are consistent with the view that O157 VTEC and possibly other VTEC may not be killed rapidly in the stomach, contributing to the low dose required to cause infection. The minimum pH for growth is affected by the type of acidulant present; acetic acid is a more successful inhibitor than lactic acid and both were more effective than HCl.[90,151]

A strain of O157 VTEC was recovered from artificially inoculated apple cider at pH 3.6 to 4.0 held at 8° C for up to 31 days; however, at 25° C, the organism survived for only 2 to 3 days.[430] The expected shelflife of refrigerated apple cider was considered to be between 2 and 3 weeks so the pathogen could survive long enough to infect a consumer. The survival of the O157 VTEC in apple cider in these investigations was significantly reduced in the presence of 0.1% sodium benzoate, either alone or in combination with 0.1% potassium sorbate. In contrast, the addition of these preservatives was found to have little effect on survival in another study of O157 VTEC in apple cider.[254] The degree of acid tolerance was strain dependent. Survival of O157 VTEC has been demonstrated during preparation of yogurt from cow's milk containing 10^3 cfu ml^{-1}.[243] The pH values achieved during fermentation were in the range of 4.4 to 4.6. After 7 days at 4° C, there was a decrease in O157 VTEC level of less than 1 log_{10} unit cfu ml^{-1}. Similar results were obtained for traditional yogurt and a product that included *Bifidobacterium bifidum* in the starter culture.

Several reports from the US have examined survival of O157 VTEC in commercial mayonnaise and salad dressings. Federal regulations in the US, formulated to ensure destruction of salmonella at a time when unpasteurized eggs were used, required the product to contain 1.4% acetic acid at a pH of ≤ 4.1[429] or 0.7% acetic acid for reduced calorie mayonnaise. Studies have compared recovery of the organism from products stored at 5° C to 7° C or at room temperature (20° C to 25° C), considered to be the normal storage temperatures for these foods. At refrigerated temperatures, O157 VTEC survived for at least 35 days and up to 55 days in mayonnaise within the pH range 3.6 to 3.9.[407,429] At room temperature, O157 VTEC were undetectable between 72 hours and 96 hours after inoculation compared with a nonpathogenic strain of *E. coli* that survived for between 24 hours and 48 hours.[300,407] In one study however, the organism was recovered from mayonnaise for up to 21 days at 20° C, although a decline of up to a 1,000-fold was observed after 7 days.[429]

Abdul, Raouf et al.[1] showed that O157 VTEC could grow in salad mixtures containing beef and between 16% and 32% mayonnaise at pH 5.94 to 5.55 and were not inactivated in the product at 5° C. Although studies of O157 VTEC contamination of mayonnaise have often used unrealistically high inoculum levels, poor handling could result in cross-contamination by raw meat, meat juices, or unwashed utensils. Organisms might not be eliminated from mayonnaise, particularly if held at refrigerated temperatures. Dilution of mayonnaise during preparation of salads and sandwiches further diminishes the antimicrobial effect of the product.

Investigations on the survival of O157 VTEC in cooked or fermented meat products are relevant to outbreaks of infection with VTEC strains of serogroups O157 and O111 in which the vehicles of infection were salami-type sausages. There was growth of O157 VTEC inoculated into a slurry of cooked ground beef (pH 5.98) at 21° C.[1] Reduction of the pH with citric or lactic acid failed to stop growth but acetic acid did inhibit the organism. Isolates of O157 VTEC survived but did not grow in commercial sausage batter that was fermented to pH 4.8, dried, and stored for 2 months at 4° C;[151] the numbers declined from 10^4 g^{-1} to 10^2 g^{-1} by the end of this period. Similar results were obtained in the presence and in the absence of starter culture. At present no data are available on the survival of O111 VTEC in fermented meats. Although the rate of inactivation of O157 VTEC increases as a product becomes more acidic,[1] it is possible that the fermentation process as applied to items such as dry cured sausage may not be relied on to eliminate O157 and other VTEC and further controls may be necessary.

In the US, survival of O157 VTEC has been assessed on meat surfaces exposed to spray washing with water or solutions of organic acids. In one study on red meat slices, spraying with 0.5% to 1.5% acetic, lactic, or citric acid at 20° C or 55° C had no significant effect on the number of O157 VTEC still present on the meat surface after 13 days at 5° C.[42] Other reports indicated that washing with these organic acids could reduce the level of the organism by between 1 and 4 log_{10} units cm^{-2} but not eliminate it.[88,100,101] The effectiveness of treatment depends on the contamination levels, spray delivery method, temperature, tissue type, and acid concentration. A pilot-scale carcass washer that would mimic abattoir conditions was used to study reduction of O157 VTEC inoculated at 10^5 cfu cm^{-2} onto tissue surfaces from beef carcasses.[88] There was no significant difference in the effectiveness of acetic, citric, or lactic acids in reducing contamination. A concentration of 5% reduced the numbers by 1 to 2 log_{10} units, with removal from adipose tissue being better than from lean surfaces. Trisodium phosphate, which has been approved in the US for control of salmonella during poultry processing, also has been shown to reduce surface contamination of beef with O157 VTEC.[216] The above findings may have relevance for the control of VTEC contamination of carcasses (see Section 43.9.2).

Several factors affect acid tolerance of O157 VTEC. Survival of O157 VTEC in acid conditions was enhanced in late logarithmic and stationary phase and in cells that had been starved at 25° C.[11] Strains of O157 VTEC that were adapted to acid conditions by culture at pH 5 had increased resistance to lactic acid and survived better than nonadapted cells during sausage fermentation and in dry salami (pH 5.0) or apple cider (pH 3.4).[234] Several acid tolerance systems appear to contribute to the survival of O157 VTEC in the environments of the stomach (pH 1 to 3) and in the intestine (pH 4.5 to 7) in the presence of fatty acids.[235] Once induced, these systems persisted during storage of the organisms at 4° C for up to 28 days. Strains of O157 VTEC adapted to pH 5 were recovered in greater numbers than nonadapted cells after inoculation into ketchup (pH 3.6) and storage at 5° C.[392] There was strain-to-strain variation in the survival times but, generally, adapted cells were recovered for 5 days.

Two studies have examined the survival of O157 VTEC strains in meats exposed to gamma irradiation. Factors affecting inactivation of the organism included temperature, atmosphere, fat content, and radiation dose. An inoculum of $10^{4.8}$ cfu O157 VTEC g^{-1} of ground beef was reduced to less than 10 cfu g^{-1} by a radiation dose of 0.75 kGy, and the organism was undetectable after exposure to more than 1.5 kGy.[384] Clavero et al.[77] calculated from irradiation inactivation curves that a dose of 2.5 kGy would kill $10^{8.1}$ O157 VTEC g^{-1} of ground beef.

Survival of O157 VTEC strains in drinking water has been examined in response to epidemiological evidence of waterborne outbreaks.[306,375] Well water collected from the water source implicated in the outbreak in Cabool had a coliform count of less than 1 organism $(100\ ml)^{-1}$. Samples were inoculated with 10^6 to 10^7 cfu ml^{-1} of O157 VTEC strains from either the Cabool outbreak or from a beefburger. There was no significant reduction in viable counts of the strains for 7 days at 5° C or 20° C. After this time, death occurred more rapidly at 20° C with a 5 $\log_{10}$ reduction after 35 days; strains survived at 5° C for at least 70 days. There appeared to be no significant difference between survival of the O157 VTEC strains and a control *E. coli* strain isolated from river water. Strains of O157 VTEC are as susceptible to the chlorination treatment used for drinking water as are other *E. coli.*[131]

43.9 CONTROL AND PREVENTION OF INFECTION

Some of the factors that affect the control of infections caused by diarrheagenic *E. coli* have been mentioned in previous sections on the epidemiology of infection and the occurrence of the organism in food and the environment. Although many general preventive measures are applicable to all the groups of diarrheagenic *E. coli,* the zoonotic nature of VTEC infections presents specific problems.

43.9.1 Diarrheagenic *E. coli* Other Than VTEC

The principal source of EPEC, ETEC, and EIEC and possibly the newer groups of *E. coli* involved in human disease appears to be the intestinal tract of affected individuals and asymptomatic carriers. In areas where disease is endemic, control in the population is achieved by improvements in sanitation, particularly the provision of safe drinking water and the disposal of sewage to avoid contamination of water supplies. The practice of fertilizing crops with untreated human sewage should be avoided. Control of flies may reduce the likelihood that they may act as vectors of infection. In developed countries where good sanitation is the norm, it is important to ensure adequate standards in recreational facilities such as campgrounds and parks.

Hygienic practices in handling and preparation of foods are of great importance. Education of food workers should include proper personal hygiene, particularly hand washing, and safe techniques that ensure adequate cooking and storage of foods under conditions to avoid bacterial multiplication. These measures are particularly important in relation to recently weaned children. The practice of prolonged breast feeding in many developing areas provides important protection against disease and avoids the use of potentially contaminated water and feeding equipment. Unchlorinated water should not be used for cleaning utensils and food contact surfaces or for cleaning or cooling in commercial food production units. Control of travelers' diarrhea is achieved by avoidance of potentially contaminated foods that are eaten raw, including salads, unwashed fruit, and unheated milk. Travelers to countries where infections due to diarrheagenic *E. coli* are common should rely on hot food and drinks or on water in sealed bottles and avoid adding ice to beverages.

Vaccines have been proposed for the prevention of infection with some groups of diarrheagenic *E. coli* strains. In the 1970s oral vaccines based on EPEC serogroups including O55, O86, and O111 were tested in field trials in infants but the efficacy of the vaccines was insufficient for routine use.[256,301] Future developments are more likely to be based on factors involved in adhesion of EPEC, such as bundle-forming pili and intimin. Numerous vaccines have been developed against infection by ETEC including live preparations and nonliving antigen mixtures that may comprise toxoids, inactivated whole cells, and purified surface antigens. Two candidate vaccines have incorporated the B subunit of CT, and one of these also contained killed whole cells of *Vibrio cholerae.*[78,374] Problems in the successful development of vaccines against human ETEC have arisen from the diversity of serogroups and the number of different colonization antigens involved and also from economic factors. This contrasts with the widespread use of vaccines to control ETEC infections in piglets and calves.[198] Studies on EAggEC and DAEC have not yet revealed suitable antigens on which vaccines could be based.

Successful treatment of *E. coli*-associated diarrhea depends on early correction of fluid and electrolyte imbalance. In the developing world, use of oral rehydration therapy is of particular importance in infection caused by ETEC. In hospitals and nurseries, measures to avoid spread of infection from patient to patient include barrier-nursing techniques and isolation of cases. The widespread environmental contamination may require closure of wards for disinfection and screening of carers for carriage of the *E. coli* pathogen.

Widespread use of antimicrobial agents for treatment of disease due to EPEC and ETEC has been questioned. The practice will lead to spread of antibiotic resistance, which is increasingly common in both these groups of organisms. In addition, some of the antimicrobial agents employed have high toxicity, particularly to young children most at risk of infection. Prophylaxis with cotrimoxazole, trimethoprim, or ciprofloxacin may reduce the duration of travelers' diarrhea.[35,114,122]

43.9.2 VTEC

Measures for control and prevention of VTEC infection should take account of the clearly identified reservoir of the organism in the intestinal tract of cattle and other food or domesticated animals and the low dose required for infection, at least with O157 VTEC. It is necessary to address and break the three major transmission routes identified as foodborne infections, acquisition of disease through direct or indirect contact with animals, and person-to-person spread.

The control of VTEC in food in Britain has been addressed recently in detail.[4] This report stated that it must be accepted that VTEC may be present on or in raw foods, particularly meat and milk that may be contaminated by fecal slurry. The factors affecting fecal carriage and excretion of VTEC in cattle appear complex, and management practices appear to influence prevalence in herds. Further investigations are needed to assess methods to minimize carriage and excretion in beef and dairy animals. The Richmond Committee on red meat production[304] made recommendations on slaughtering that are highly relevant to control of VTEC. These related in particular to reducing contamination of carcasses with gastrointestinal contents and the use of equipment that combines high throughput with ease of cleaning. Microbiological monitoring of key equipment was seen as a check of cleaning and disinfection processes.

There have been several studies from the US on the use of carcass washes particularly with hot organic acids (see Section 43.8.2), but the relative resistance of O157 VTEC to low pH may limit their usefulness. The US Food Safety and Inspection Service has approved the use in beef processing plants of a steam vacuum sanitizing system delivering water at 88° C to 94° C onto carcass surfaces. In laboratory experiments O157 VTEC applied in fecal slurry on beef carcass samples were reduced from a level of 7.6 $\log_{10}$ cfu cm^{-2} to about 2.1 $\log_{10}$ cfu cm^{-2} by this treatment.[104] A further study[105] examined the fate of O157 VTEC on carcass samples that had been spray washed at 32° C and then stored at 5° C for 21 days. Washing with organic acids or trisodium phosphate reduced the initial inoculum from 4 $\log_{10}$ cfu cm^{-2} to less than 1.3 $\log_{10}$ cfu cm^{-2}, which was maintained over the storage period. In contrast, there was growth of O157 VTEC on water-washed beef tissue after 2 days' storage.

The application of the Hazard Analysis Critical Control Point (HACCP) system will provide a structured approach to the prevention or limitation of VTEC in the food supply. This approach is based on use of data on the occurrence, survival, and growth of VTEC in foods to identify stages in food production, manufacture, storage, or supply to the consumer that pose a hazard. One such critical point is the supply of raw materials. Control may be achieved by purchase from hygienic, inspected sources according to an established specification to maintain quality assurance. This is particularly important for the production of minced meat items such as sausages and beefburgers in which organisms contaminating meat surfaces become distributed throughout the final product. Hazards associated with these foods could be further reduced by informative labeling indicating safe storage, handling, and cooking procedures.

Following an investigation of the central Scotland outbreak, the Pennington group published a detailed final report.[291] There were 32 recommendations in eight major areas covering all aspects of food production and consumption from "farm to fork." The present, and also the last, UK government accepted all the recommendations.

A different approach to control of O157 VTEC in raw ground beef has been adopted in the US. The Food Safety and Inspection Service declared in 1994 that *E. coli* O157:H7 was an adulterant in this product and that contaminated lots be excluded from commerce and either destroyed or reprocessed to kill the organism.[196] In 1997, approximately 25 million pounds of ground beef produced at the Hudson Foods, Columbus, Nebraska, plant were recalled.[225] An outbreak in Colorado was associated with consumption of burgers from particular lots of frozen beef patties produced by Hudson Foods. Protocols for sampling at production plants, laboratory testing, and regulatory procedures have been established, and the Inspection Service has legal authority to impose these measures. In view of the vast size of the ground beef industry in the US and the difficulty of realistic sampling, the value of these procedures is uncertain unless controls also are imposed to minimize initial contamination at farms and abattoirs.

The continued availability of raw cow's milk in England, Wales, and Northern Ireland remains controversial. Raw milk has been associated with O157 VTEC infection as well as with outbreaks caused by *Campylobacter* and *Salmonella* and may pose a particular threat for vulnerable groups including children. A recent report[4] proposed reconsideration of the legislation that would require obligatory pasteurization of milk, as is practiced in Scotland. Studies on survival of O157 VTEC at low pH have indicated that products such as cheese and yogurt made from raw milk must also be subject to more stringent control.

Elimination of VTEC by heating is one of the major control points in the food chain. Pasteurization of milk by procedures already defined by legislation should ensure a product that poses no threat to human health. However, one recent incident has emphasized the need to prevent postpasteurization contamination. There have been extensive investigations on cooking procedures to destroy VTEC in minced meat products, particularly O157 VTEC in fresh and frozen beefburgers.[4] Most data suggest cooking so that all parts of the burger are maintained for 2 minutes at 70° C, or equivalent values, until juices run clear and there are no pink bits inside. However, factors such as meat composition, size, thickness, and whether the item is chilled or frozen will affect adequate cooking times. Raw beefburgers and other minced meat products should be supplied with cooking instructions adequate to destroy VTEC and that take account of different cooking techniques that may be used.

As described in previous sections, outbreaks of infection with O157 and other VTEC have been associated with fermented but unpasteurized foods such as apple cider and sausage. The use of minimally contaminated starting materials and microbiological monitoring are essential to reduce hazard because the fermentation processes involved may not be relied on to provide control. Preservatives such as sodium benzoate may increase the safety of apple cider.[430]

The potential for cross-contamination is a major concern throughout the chain of food production and particularly in the domestic kitchen and catering environments. Guidelines for avoiding direct and indirect cross-contamination are available from a number of sources.[4,291] As it is unlikely that VTEC will be eliminated from the food chain, education and training in food hygiene are important for commercial food handlers and consumers. Increased public awareness generated by government and retailers could reduce sporadic cases and small family outbreaks that may be the result of poor food handling in domestic kitchens.

Recent reports of VTEC carriage by a range of animals in addition to cattle have indicated that animal contact is a risk factor for human infection. Farmers have a responsibility to ensure a safe working environment and appropriate control measures. More studies are required to assess the prevalence of VTEC in adults working with livestock on farms and in abattoirs. The observance of simple hygiene procedures by members of the general public attending farm visitor centers is the most important preventive measure for infection with VTEC.[91] Handwashing facilities should be easily accessible and their use strongly encouraged before eating and drinking. Visitors should be made aware of potential hazards by leaflets or notices. Young children should be supervised to ensure adequate hand washing. Designated eating areas must be clearly separated from enclosures with animals and should, where possible, be outside the main farm areas.

Recommendations for the control of infections caused by VTEC in England and Wales are based on those for *Shigella sonnei* infections. They take account of the potential severity of disease, the low infectious dose, and the particular hazard to young children.[372] The importance of good hygiene practices is stressed, particularly the provision of toilet facilities, hand washing, and formal procedures for cleaning of nursery and school environments and equipment. It has become clear that O157 VTEC may be harbored asymptomatically or may be excreted for long periods after onset of symptoms. Although generally, individuals may return to school or work after diarrhea has ceased, some groups pose a special risk of spreading infection. These include food handlers, health care workers, preschool children attending a daycare facility, and older children or adults who are unable to implement adequate personal hygiene for personal or environmental reasons. Exclusion of the individuals from the first three groups has been recommended until negative cultures have been obtained from two consecutive fecal samples obtained 48 hours apart. Contacts of persons in the special groups should also be excluded until the household case is asymptomatic.

Infection with VTEC is usually self-limiting, and the value of antimicrobial therapy for disease caused by O157 VTEC has not been established. The duration of symptoms was not reduced by treatment and there may be an increased risk of HUS.[422] Evidence from North America, England, and Wales suggests that resistance to antimicrobial agents is becoming more prevalent in O157 VTEC strains;[215,386,412] however, multiple resistance, such as encountered in *Salmonella* and *Shigella,* is very rare. The use of antimotility agents to treat bloody diarrhea caused by O157 VTEC was significantly associated with progression to HUS.[75] There are no vaccines available for the prevention of VTEC infection.

43.10 CONCLUDING REMARKS

Diarrheagenic *E. coli* form a complex group of organisms that fall into different classes with contrasting properties. Different reservoirs, modes of transmission, and epidemiology pose various problems both clinically and with regard to the role of foodstuffs. It is important to recognize the continued threat posed by *E. coli* as a diarrheal pathogen. Whereas the importance of EPEC, ETEC, and EIEC has declined in developed countries, VTEC have emerged and may constitute a more far-reaching problem because of their presence in food animals. It appears likely that EAggEC will also be recognized as a significant cause of diarrheal disease although much more work is needed on these organisms.

There is a need for better tests to identify diarrheagenic *E. coli* in clinical specimens and foods. This is particularly relevant for VTEC strains other than O157. Lack of tests for these organisms has hindered assessment both of their prevalence and their status as pathogens. In the absence of convenient biochemical markers, tests for non-O157 VTEC and EAggEC may be based on properties associated with pathogenesis. At present it is likely that there is considerable under-recognition of sporadic cases and outbreaks of diarrhea due to *E. coli*, and this will continue as long as many tests are available only in reference laboratories.

In relation to the food chain, further studies are required to identify reservoirs and vehicles of infection with diarrheagenic *E. coli*. For EAggEC, the role of foods is not yet established and it is not known whether these organisms are harbored by agricultural livestock. Although these aspects have been studied in relation to O157 VTEC, it has become clear that spread of the organism can be much more complex than the originally identified link with consumption of ground beef and raw milk. Further studies should include non-O157 VTEC and consider factors affecting animal carriage, the application of hygiene practices in the early stages of red meat production, and the search for other vehicles of infection.

The relevance of diarrheagenic *E. coli* to the food industry centers at present on VTEC. All sectors should adopt a HACCP-based approach for control of these organisms. Manufacturers should be aware that modifications of processes, possibly in response to economic factors or the demands of modern consumers, may have microbiological significance with respect to the survival of contaminating organisms. Education and training of workers should have increased priority at all levels of food production. However, good communication with the consumer may be one of the most effective approaches for control of diarrheagenic *E. coli* and other enteric pathogens. Advice should be available on health and hygiene and clear guidelines produced on food preparation and cooking communicated by means of informative labelling. These measures could be put in place by the government, consumer organizations, and the food industry.

44.1 INTRODUCTION

The history of *Listeria monocytogenes* dates back to at least 1918, when Dumont and Cotoni[125] isolated from cerebrospinal fluid (CSF) an organism that was deposited at the Pasteur Institute in Paris and later identified in 1940 as *L. monocytogenes*.[394] Murray et al.[367] described the organism first in 1926 and named it *Bacterium monocytogenes* because it caused a mononuclear leucocytosis in rabbits. Pirie,[403] a few years later, isolated a bacterium from a gerbil in South Africa, which he named *Listerella hepatolytica* in honor of Lister; therefore, the name listerellosis was used to describe the disease process caused by this organism for some time. When it was discovered that *Bacterium monocytogenes* and *Listerella hepatolytica* were the same organism, and that the name *Listerella* already had been given to a group of slime molds, it was decided to change the name of *Bacterium monocytogenes* to *Listeria monocytogenes*.[403] The emergence of this "awkward and unnoticed adolescent"[211] into an important foodborne pathogen has been quite dramatic. Since

1985, when the organism was identified as the causative agent in a large (142 cases with 48 deaths) foodborne outbreak involving Mexican-style soft cheese,[306] it has been a source of continual problems for the food industry and regulatory agencies. The estimated annual costs and productivity losses for human listeriosis in the United States (US) were recently given as $209 to $233 million.[521] These figures, however, do not include the economic losses to the various food companies caused by the recall of *L. monocytogenes*-contaminated product, as well as *Listeria* control costs. In one survey involving 17 meat producers, *Listeria* control costs totalled $9.3 million, or roughly 0.1% to 0.2% of sales.[427] Thus, the importance of this organism not only from a human health, but also from an economic standpoint, has led to a dramatic surge in interest among food manufacturers and regulatory bodies. The following sections will discuss some of the important features of this foodborne pathogen.

44.2 TAXONOMY AND PROPERTIES OF *L. MONOCYTOGENES*

44.2.1 Taxonomy

In the seventh edition of *Bergey's Manual of Determinative Bacteriology* (1957), *L. monocytogenes* was listed in the broad grouping of the family *Corynebacteriaceae*, mainly because of similarities in morphology. In the eighth edition,[452] the organism was placed in a grouping (with two other genera, *Caryophanon* and *Erysipelothrix*) called "genera of uncertain affiliation." At this time, three other species were included in the genus, namely, *L. denitrificans, L. murrayi,* and *L. grayi. L. denitrificans* also has now been moved to another genus and is referred to as *Jonesia denitrificans*,[431] while *L. murrayi* and *L. grayi* were merged to form a single species: *L. grayi.* The use of 16S ribosomal RNA partial sequencing showed that *L. monocytogenes* belonged within the *Clostridium* subbranch along with *Brochothrix*, *Staphylococcus*, *Streptococcus*, and *Lactobacillus.*[317] These findings were taken into account in *Bergey's Manual of Systematic Bacteriology* published in 1986,[453] where the genus *Listeria* was placed in a section called "regular, nonsporing, Gram-positive rods," with six other genera, including *Brochothrix*, *Lactobacillus*, *Kurthia*, *Renibacterium*, *Caryophanon*, and *Erysipelothrix.* In the latest (1994) edition of *Bergey's Manual*, *L. monocytogenes* was placed in Group 19, again referred to as "regular, nonsporing, Gram-positive rods."[234] The only genus added to this group in this edition was *Carnobacterium.* Group 19 contains genera placed together mainly for convenience in strain identification, and the genera share only a few similarities in terms of physiological or morphological characteristics.[234]

Evidence obtained from sequencing the flagellin, listeriolysin, and invasive-associated protein genes has provided evidence that *L. monocytogenes* exists in at least three evolutionary lines, with a strong degree of conservation within those lines.[419] Most isolates, however, belong to only two of the sequence types for which there is a correlation with flagellar antigens, as well as grouping based on pulsed-field gel electrophoresis (PFGE),[56] multilocus enzyme electrophoresis (MEE),[39] randomly amplified polymorphic DNA (RAPD) typing,[335] and restriction fragment length polymorphism (RFLP) analysis.[512,536] In most studies, division I contains serotypes 1/2a, 1/2c, 3a, and 3c, whereas division II includes serotypes 1/2b, 3b, 4b, 4d, and 4e. Serotype 4a isolates appear to form a distinct homogenous group,[419] while serotype 4b strains can be further divided into at least two groups.[131,536]

44.2.2 General Properties

Listeria species are short, Gram-positive, nonsporeforming, facultatively anaerobic rods, which are motile by means of a few peritrichous flagella. Motility occurs from 20° C to 25° C, but not at 37° C. Transcription of the gene encoding flagellin is pronounced at 22° C, but is undetectable at 37° C.[119] Interestingly, *L. innocua* produced larger amounts of flagellin at 37° C than *L. monocytogenes* and often is motile at this temperature.[270] This suggests that significant differences exist between the two species in their regulation of flagellin gene expression at 37° C.

Listeria spp. are psychrotrophic organisms, capable of growing at refrigeration temperatures; they are a concern in extended shelf-life, refrigerated foods. The ability of the organism to grow over a wide temperature range in acidic environments, as well as in the absence of or at very low amounts of O_2, enables it to multiply in many environments. The organism is widespread (Figure 44–1) and can be found in many locations such as water, silage, sewage, slaughterhouse waste, milk of normal and mastitic cows, and human and animal feces.[142,319,505] A seasonal variation in human fecal carriage of *L. monocytogenes* has been reported.[319] It has also been suggested that the plant-soil rhizosphere may be a natural habitat for *Listeria* spp.[505]

44.3 CHARACTERISTICS OF THE DISEASE

44.3.1 Incidence and General Characteristics

Most cases of human listeriosis appear to be sporadic, although a portion of these sporadic cases may be common source clusters that were previously unrecognized.[80] The true rate of human listeriosis worldwide is underestimated because most available data are based on voluntary reporting. The reported incidence of listeriosis varies from 0.2 to 8.3 cases per million population, with most cases being reported in industrialized countries (Table 44–1).[428,430] Higher incidence rates, however, have been reported in some countries.[142,378] Although it is considered that as many as 80% to 90% of human listeriosis cases are linked to the ingestion of contaminated food, demonstration of foodborne transmission occurs infrequently, and generally is due to unusual circumstances.[63,306] Listeriosis can also be acquired

by direct contact with infected aborteous material from animals,[437] by nosocomial cross-infection,[151,339] and by means of aerosolization. The majority of human cases occur in individuals who have an underlying condition that leads to suppression of their T-cell mediated immunity. Skogberg et al.[465] found that 43% of 74 cases of systemic listeriosis in Finland had received immunosuppressive therapy within 1 week before the onset of listeriosis, and concluded that prior immunosuppressive therapy is an important predisposing factor for listeriosis. Table 44–2 lists the most common underlying conditions of cases of listeriosis reported worldwide. Patients with acquired immunodeficency syndrome (AIDS) have been reported to be 280 times[448] more susceptible to listeriosis than is the general population, and *L. monocytogenes* is now recognized as an important opportunistic pathogen in human immunodeficiency virus (HIV) infected individuals.[264]

Using data collected from France and the US, high-risk individuals can be ranked by decreasing risk as follows:[429] organ transplant recipients (200 cases per 100,000 patients); patients with AIDS (115 cases per 100,000 patients); HIV-infected patients (52 cases per 100,000 patients); pregnant women (4.7 to 30 cases per 100,000 live births); cancer patients (13 cases per 100,000 patients); and the elderly (1.4 cases per 100,000 individuals over 65 years old). Several factors may increase the susceptibility of individuals to listeriosis, for example, the use of antacids and laxatives.[229,448] The decreased gastric acidity resulting from the use of antacids may increase the number of organisms that survive passage through the stomach, ultimately resulting in a lower minimum infectious dose. Laxatives are known to alter transit time and modify the intraluminal environment of the gastrointestinal (GI) tract.

It is not known why the incubation period of listeriosis varies so much (more than 24 hours to 91 days). It is possible that the dose of organism ingested, the host immune system, and any intercurrent viral or bacterial infection all play some role in determining the period of onset of the illness after initial exposure to the organism.

Worldwide figures for human listeriosis reported for the years 1989 and 1990 show that 43% and 34.3% of the total cases reported were maternal and neonatal infections, respectively.[428,430] During pregnancy, maternal immune reactions are suppressed. Studies with mice have shown an apparent decrease in *Listeria*-specific cellular reactions during pregnancy (ie, there were abnormalities in the spleen dendritic cells).[280] The proportion of cases involving pregnant women or various groups of immunosup-

Table 44–2 Underlying Conditions of Adults with Listeriosis

pressed individuals in a certain geographical area tends to reflect the characteristics of the local high-risk population.[78] Women who present with preterm labor should be suspected of being infected until proven otherwise. Recurrent cases of human listeriosis can occur and are thought to be due to treatment failure.[345] The major manifestations of the disease in nonperinatal cases are septicemia and/or meningitis. In the US *L. monocytogenes* is the fifth most common cause of bacterial meningitis and is the most common organism causing meningitis in patients with underlying malignancies. It is the third leading cause of bacterial neonatal meningitis in the United Kingdom (UK).[483] Unique features of listeria meningitis include

- common occurrence of tremor, grand mal, and focal motor seizures;
- direct invasion of the cerebral cortex;
- most commonly invading the brain stem (rhomboencephalitis);
- the percentage of neutrophils in the CSF is lower than in meningitis caused by other bacteria, and there is often a high monocyte count in cases of listerial meningoencephalitis; and
- in keeping with the organism's intracellular habitat (see Section 44.4), Gram-stained smears of the CSF usually are negative.[474]

The tropism of *L. monocytogenes* for the central nervous system (CNS) remains unexplained, although it is known that CNS cases are associated with a high mortality rate and neurological sequelae among survivors. Studies in Denmark and Australia also have pointed to the importance of *L. monocytogenes* as a nosocomial pathogen.[258,396] The differential diagnosis and treatment of *L. monocytogenes* infections are shown in Table 44–3.

44.3.2 Neonatal Listeriosis

L. monocytogenes is one of the few bacteria able to cross the placenta and gain direct access to the fetus. This property leads to the unique clinical syndrome of granulomatosis infantisepticum, which is fatal in 35% to 55% of cases in newborn infants.[475] The organism has been found in amniotic fluid at levels of 10^8 cfu ml^{-1} [88] and has been shown, using an *in vitro* uterine strip-model, to be possibly involved in causing premature labor contractions.[295] An interesting report also described a case of listeriosis in a full-term (39 weeks, 3 days) infant where the placenta became infected (ie, placental cultures positive, whitish nodules, and microabscesses present on macroscopic examination), but not the fetus. The infant, normal at birth, later developed severe neurological sequelae, possibly because of placental damage altering the utero-placental blood flow, thus leading to fetal hypoxia.[6]

Infection in pregnant women usually results in a mild flu-like illness. Although it can occur at any time, infection of the fetus usually occurs in the third trimester and can lead to abortion, stillbirth, or delivery of an acutely ill baby, although more commonly infection presents as preterm labor. Maternal listeriosis does not always result in infection of the fetus, as has been demonstrated in cases where only one of a set of twins became ill.[331] An interesting study showed that women who carry more than one child have a nearly 4-fold greater risk of acquiring listeriosis than pregnant women with singletons.[331] This risk of listeriosis in multiple-gestation pregnancies was also associated with age (ie, with women more than 35 years). Besides the well-known factors of reduced fetal and maternal immunity during pregnancy, in multiple-gestation pregnancies compared with single births, there may be increased production of hormones or other immunological effectors in the larger placenta.[331] Cases of first- and second-trimester listeriosis have occurred where treatment of the infected mothers led to the delivery of healthy babies.[169,176] Healthy pregnant women may be carriers of the organism and still give birth to a healthy child. Several cases of listeriosis in pregnant women with impaired immunity have led to the suggestion that in this group of individuals, listeriosis may be an important unrecognized disease.

Two clinical forms of neonatal listeriosis are known: early and late onset. In early-onset listeriosis

Table 44–3 Differential Diagnosis and Treatment of *Listeria monocytogenes* Infections

Category	*Differential Diagnosis*	*Treatment*
Pregnancy infections	Influenza Pyelonephritis Septic abortion	Ampicillin or penicillin
Granulomatosis infantiseptica	Neonatal sepsis Neonatal meningitis due to enteric bacilli or group B streptococcus	Ampicillin and gentamicin
Sepsis	Sepsis of unknown source due to a large variety of organisms	Ampicillin or penicillin
Meningoencephalitis	Psychiatric illness or metabolic encephalopathy Infection due to *Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis,* or *Cryptococcus neoformans* in immunosuppressed patients or to group B streptococci or enteric bacilli in neonates	Ampicillin or penicillin, possibly with gentamicin intrathecally
Cerebritis	Brain abscess, tumor, stroke	Ampicillin or penicillin
Focal infections	Varies with site	Ampicillin or penicillin

Source: Adapted with permission from G.L. Armstrong, M.P. Doyle, and J.E. Bennett, *Principles and Practices of Infectious Diseases*, 4th ed., G.L. Mandell, J.E. Bennett, and R. Dolin, eds., p. 185, © 1994, Churchill Livingstone.

(0 to 2 days after birth) infection occurs in utero, while in late-onset cases (more than 5 days after birth), infants are either colonized at birth with a delayed onset of infection or disease is acquired by cross-infection from environmental sources. The majority of cases observed fall into the early-onset category. Most neonatal deaths from congenital listeriosis appear to be due to pneumonia and respiratory failure. It is not known why CNS infections, although common in nonperinatal cases, are rarely observed in pregnant women.[339]

Possible diagnostic features of neonatal listeriosis include bright green meconium, the presence of miliary granulomata and microabscesses in the placenta, and the presence of Gram-positive bacilli in clinical specimens. Early diagnosis and treatment are crucial to the survival of the infected neonate. Gram-staining of the gastric aspirate may be a reliable test for the early diagnosis of listeric infection. There is no definitive evidence that listeriosis is associated with repeated spontaneous abortions or infertility. Despite modern antibiotic therapy, neonatal listeriosis still has a mortality rate of about 35%.[142,339] Factors associated with a fatal outcome include low birthweight, early gestational age, and a long interval between symptom onset and delivery of antibiotics.

44.3.3 Noninvasive Listeriosis

Although noninvasive syndromes have been well characterized for some of the better-known foodborne pathogens such as *Clostridium perfringens* and *Bacillus cereus,* mild illness due to *L. monocytogenes* has not been well characterized. There are instances where only a mild, upper GI illness occurs after the ingestion of food containing the organism.[95,413,426] Such mild cases would go unnoticed unless they were part of a common-source outbreak. It is not known how many mild cases occur each year or what the ratio of noninvasive to invasive cases is.

44.3.4 Healthy Carriers

L. monocytogenes is a normal resident of the intestinal tract in humans and can be found in from 2% to 6% of samples analyzed from a variety of different populations, including pregnant women, healthy individuals, and those with various symptoms or underlying illnesses.[267,291,318] The reported incidence of the organism in feces depends on the methodology used and the number of fecal specimens submitted for analysis.[318] Carriage of the organism is more common, however, in sporadic cases and in household contacts of listeriosis patients than in the general population. Of 82 individuals from 28 households in which a case of listeriosis had occurred, 15 household contacts (18%) carried *L. monocytogenes* with the same serotype and enzyme type as the corresponding case-patient.[449] However, there was no significant difference in the presence of GI or other symptoms between carriers and noncarriers. Secondary cases of listeriosis occur rarely, and host susceptibility plays a crucial role in determining the outcome of the host's exposure to this organism. In sporadic cases, the proportion of excretors was high (21.6%), with levels of the organism reaching 10^4 organisms g^{-1} of feces.[256] Fecal excretion of the organism can last for at least 2 weeks. A study in the UK suggested that carriage may be seasonal, being more common in July and August. Studies with pregnant women[212,267] and renal transplant patients[318] demonstrated that even in high-risk groups, fecal carriage does not necessarily lead to clinical illness; thus, fecal screening for this organism as an indication of recent or current infection, or analysis of fecal samples during pregnancy to indicate a risk of listeriosis, is not warranted.[212]

44.3.5 Serotypes Involved in Listeriosis

Although human listeriosis can be caused by all 13 serotypes of *L. monocytogenes,* the majority of cases are caused by only three serotypes: 1/2a, 1/2b, and 4b. Geographic differences in serotype prevalence are seen: although 4b predominates in many European countries, there appears to be an even distribution of serotypes 1/2a, 1/2b, and 4b in cases of listeriosis in Canada and the US and a predominance of serotypes 1/2a and 1/2b in cases in countries such as Australia and Hungary.[430] The reasons for the differences in serotype distribution are unknown. It is unclear why only three serotypes cause most of the illnesses, although it has been suggested that these serotypes are more pathogenic than the others. Most of the large listeriosis outbreaks have involved a limited number of clones of serotype 4b, leading to the hypothesis that these constitute "hot" clones that are more virulent than other strains.

44.3.6 Strain Typing

Because most listeriosis cases are caused by only three serotypes, serotyping is of limited value in epidemiological investigations. Phenotypic methods such as biotyping, phage-typing, bacteriocin-typing, and MEE are used to differentiate strains. Many of these methods need specialized reagents, and only a few reference laboratories around the world can perform them reliably. Other problems with some phenotypic methods include nontypeability of strains and nonreproducibility. Phage typing is still used widely to type strains of *L. monocytogenes* and has proven to be useful in the screening of large numbers of strains in outbreak situations.[252] In studies of nearly 100 strains of *L. monocytogenes*, phage typing was the most discriminatory of four typing methods evaluated, followed by restriction endonuclease analysis (REA) typing, MEE, and ribotyping.[377,379] There have been recent attempts to optimize the current internationally accepted phage typing system for *L. monocytogenes.*[327] In general, phage typing is not considered to be as reproducible or discriminating as most molecular typing methods except for ribotyping.[21,45] However, phage typing is very suitable for mass screening of strains, when cost and complexity of handling are taken into account. Other typing methods for *L. monocytogenes* that are useful for mass screening include esterase,[195] monocin,[21] and lectin[133] typing.

In using MEE for typing, bacterial strains are differentiated according to the variation in electrophoretic mobility of a variety of enzymes. The diversity revealed allows differentiation of a number of electrophoretic types (ETs) within a single microbial species, with the combination of all electromorphs obtained for a strain being referred to as an ET. MEE has been applied successfully to *L. monocytogenes.*[39,44,223,380,400]

Some of the current genotypic methods used for typing strains of *L. monocytogenes* can be seen in Table 44–4. The same food sample may contain more than one clone or strain of *L. monocytogenes,*[102,309] and thus, depending on the reasons for typing, consideration must be given to the number of colonies isolated and/or tested from a selective plate.

Chromosomal DNA restriction analysis, REA, was one of the first chromosomal DNA-based typing methods used for *L. monocytogenes.*[523] In this method, chromosomal DNA is isolated, cut with a frequent-cutting restriction enzyme, and electrophoresed on agarose gel. The separated fragments, which usually range in size from 1,000 to 20,000 bp, are then visualized by staining with ethidium bromide. The complexity of the banding patterns obtained can limit the usefulness of the method because numerous bands are obtained when using a 4- or 6-base cutter against whole chromosomal DNA.

Table 44–4 Some Examples of Molecular Typing of *L. monocytogenes* by Genotypic Methods

Typing Method	*Number of Strains Analyzed*	*Number of Profiles Obtained*	*Number of Primers or Enzyme Type Used*	*Comments*	*Reference*
RAPD	51	29, 31	2	15 isolates from two outbreaks, plus 36 epidemiologically unrelated isolates	313

PCR, Polymerase chain reaction; CHEF, Contour-clamped homogenous electric field gel electrophoresis; FIGE, Field-immersion gel electrophoresis.

Ribotyping refers to the use of DNA probes to recognize ribosomal genes. Ribosomal RNA (rRNA), present in all bacteria, makes up approximately 82% of the total RNA in a typical (ie, *E. coli*) bacterial cell and is composed of three molecular species: 23S, 16S, and 5S rRNA. The genes coding for rRNA are highly conserved (ie, the rRNA genes in many different bacteria are very similar). While most bacterial genes are present in only one copy, rRNA (or *rrn*) operons can be present in from 2 to 11 copies per bacterial cell, with *L. monocytogenes* containing 5 copies.[238] The more copies of a *rrn* operon present in a particular bacterial species, the more discriminatory ribotyping will be. In practice, the bacterial chromosomal DNA is isolated, and a restriction enzyme is used to cut the DNA into many small fragments. Once the restricted DNA has been electrophoresed on agarose gel, it is transferred either electrophoretically or by capillary action onto nylon or nitrocellulose membrane and then probed with labeled probes containing (usually *E. coli*) rRNA sequences. Besides good reproducibility, ribotyping has the advantage that universal probes can be used because of the similarity of ribosomal genes. The method has been automated using the Riboprinter™ Microbial Characterization System (E.I. Dupont, Wilmington, DE). This system divides the whole process into seven stages, and can ribotype 32 strains in four batches within 16 hours (Technical Literature, Dupont Riboprint™, E.I. Dupont). Graves et al.[209] examined 305 *L. monocytogenes* isolates from clinical and nonclinical sources and found that overall, MEE typing was more discriminating than ribotyping, but that in some cases, ribotyping was able to further subtype isolates that fell within the same ET. Ribotyping has also been found to be less discriminating than PFGE or RAPD analysis.[313]

Besides traditional ribotyping methods, there are different variations of the method that can fall under the general heading of southern hybridization fingerprinting. In this technique, instead of using rRNA as a probe, any other labeled probe that can identify a complementary DNA molecule among other DNA fragments in a gel is used. For example, probes containing toxin genes, insertion sequences (also referred to as insertion sequence or IS typing), or bacteriophage DNA can be used.[415]

PFGE typing is a method that tries to eliminate some of the problems that occur with REA, where hundreds of different bands can appear. PFGE uses restriction enzymes that are infrequent cutters, giving a small number (5 to 20) of very large, well-resolved bands, typically ranging in size from 10 to 800 kb. PFGE has been used to compare *L. monocytogenes* strains involved in outbreaks,[61,252] as well as to discern genome size differences in the different serovars of *L. monocytogenes.*[73] Genomic divisions delineated through PFGE, as well as through MEE, correlate directly with flagellar H antigen types and, therefore, to the serovars of listeriae.[39,56]

RAPD typing is one of the newer genotypic methods based on the polymerase chain reaction (PCR) (see Chapter 64). The use of PCR for RAPD differs slightly from the "normal" PCR reaction in two major respects: (1) the primers used are short (only 9 or 10 mers or nucleotides) and the sequences are chosen at random, thus no prior knowledge of the target DNA sequence is needed, and (2) the annealing temperature for RAPD is lower than for a normal PCR, and a single primer with no known homology to a genome can anneal at sites for which the match is imperfect. Purified DNA can be used for RAPD, but whole bacterial cells or supernatants from boiled cells are more convenient and equally effective.[335,336] Although there are advantages to RAPD typing, the major concern has been with reproducibility. Recent work, however, with *L. monocytogenes* (Table 44–4) has shown that the method can be reproducible under carefully controlled conditions. The method has been used successfully for strain discrimination in sporadic cases or outbreaks of listeriosis and to map the distribution of the organism in fish,[102] dairy,[514] and poultry processing plants.[294] A relatively new genotypic typing method also based on the PCR has been described.[257,288] The method takes advantage of the heterogeneity found in the spacer regions that exist between rRNA genes in microorganisms, ie, for a particular strain, multiple bands obtained after amplification represent spacer regions of various length in different ribosomal operons. In this method, however, instead of using arbitrary primers as in RAPD, one has to have some knowledge of the rRNA sequence. This technique has promise as an alternative to traditional *L. monocytogenes* typing methods.[288,472] The advantages of PCR ribotyping are that universal bacterial primers can be used; PCR-ribotyping produces stable, easily detectable amplification patterns in a rapid manner; and it has the potential to be widely useful in molecular epidemiology.[288] Its main disadvantage is its lower discriminatory power compared with PFGE, and possibly RAPD, typing.

Genotypic typing methods have increased greatly our ability to discriminate between strains of *L. monocytogenes.* None of the present subtyping methods can be used, however, to identify which strains of the organism are nonpathogenic, or less virulent.[342]

44.4 VIRULENCE

44.4.1 Virulence Factors

L. monocytogenes has an unusual life cycle. By a complicated series of host-pathogen interactions, the organism is able to enter a host cell, move across the cell cytoplasm, and enter neighboring host cells without becoming exposed to the extracellular environment (Figure 44–2).[456,474] Recently, many of the virulence factors and their respective genes have been identified, with eight of these genes grouped in a polycistronic cluster on the chromosome under the regulation of the *prfA* gene product (Figure 44–2).[75] The pathogenicity of the organism is thus multifactorial, resulting from the activity of products of at least nine genes.[342]

In foodborne infections, *L. monocytogenes* is consumed in contaminated food and possibly enters the host via intestinal epithelial cells[268] or the M cells of Peyer's patches. The bacteria then are internalized within a membrane-bound phagosome and transported to the liver, where they enter the hepatocytes by an induced phagocytosis.[484] Leukocytes rapidly are marshaled to the foci of infection, where they appear to cause the destruction of the infected hepatocytes.[84] The bacteria then are released into the extracellular space, where some are ingested and destroyed by phagocytes. Two surface proteins, internalin and p60, have been implicated in the induced internalization of *L. monocytogenes* by nonprofessional phagocytes (Figure 44–2).[180,286] Internalin was identified in screening a library of Tn*1545* mutants with the finding that, in mutants defective for entry into Caco-2 intestinal epithelial cells, the transposon had inserted into a region upstream from two open reading frames (ORF), *inlA* and *inlB*.[180] Internalin, the product of *inlA*, is a 90-kDa protein with a signal sequence, two regions of repeats, and a COOH-terminal hydrophobic region that is likely to be a membrane anchor.[123,180] Region A consists of 15 highly conserved, leucine-rich repeats (LRR). The receptor for internalin has been identified as E-cadherin, a surface protein involved in cell-to-cell binding.[355] InlB, the protein encoded by *inlB*, is a 630-amino acid protein containing 8 LRR with homology to those of internalin, and no membrane anchor.[123] *InlA* and *inlB* seem to be part of a multigene family, as several sequences showing homology are present on the chromosome.[123,180] A novel 30-kDa protein has been identified as a member of this multigene family and has been designated internalin-related protein.[305] Perhaps this *inl* repertoire encodes surface proteins with different specificities, as it has been shown that *inlA* and *inlB* gene products are essential for entry into epithelial cells and hepatocytes, respectively.[124] However, an additional *inlAB*-independent mechanism may exist, though an *inlAB* mutant was 50- to 100-fold less invasive for Caco-2 cells than the parent strain, because the mutant was still able to enter the cells.[179] Internalin is expressed more strongly at 37° C than at 20° C, and is under the control of the regulator gene *prfA*, though it is on a different region of the chromosome from the *prfA* regulon (Figure 44–2).

Spontaneous rough mutants of *L. monocytogenes*, that produce reduced levels of a 60-kDa protein called p60, form long chains and show reduced adherence, invasiveness, and virulence.[286,287] Deletions of the gene coding for p60, *iap* (invasion-associated protein), are lethal.[286] The *iap* gene encodes a 484-amino acid protein with a signal sequence but no membrane anchor, which is likely to be a mureine hydrolase involved in septum formation.[529] Its exact role in invasion is unclear,[227] but perhaps the lowered invasiveness of the rough mutants can be explained by the long chains in which they are associated.

Part of the process of internalization involves the ability of these bacteria to react with host cell–receptor molecules to induce their own phagocytosis. Two host protein kinases become tyrosine-phosphorylated during invasion of the host cell by *L. monocytogenes*. Inhibition of this process by protein tyrosine kinase inhibitors blocks *L. monocytogenes'* entry into host epithelial cells, suggesting that *L. monocytogenes* activates a protein kinase during invasion.[485,509]

Once internalized within a phagosome, which is a toxic environment for bacteria, *L. monocytogenes* lyses the membrane of the vacuole after about 30 minutes and gains access to the cytoplasm, where it can multiply. Two proteins, listeriolysin O (LLO), the first identified listerial virulence factor,[350] and a phosphatidylinositol-phospholipase C (PI-PLC)[202,469] are involved in this lysis. LLO, a 58-kDa protein, is a member of the family of pore-forming, thiol-activated cytolysins, of which streptolysin O is the prototype.[350] It is encoded by *hly*, the third gene in the *prfA* regulon. When this gene was cloned into *Bacillus subtilis*, it enabled that bacterium, after internalization within a macrophage, to disrupt the phagosomal membrane and grow within the mac-

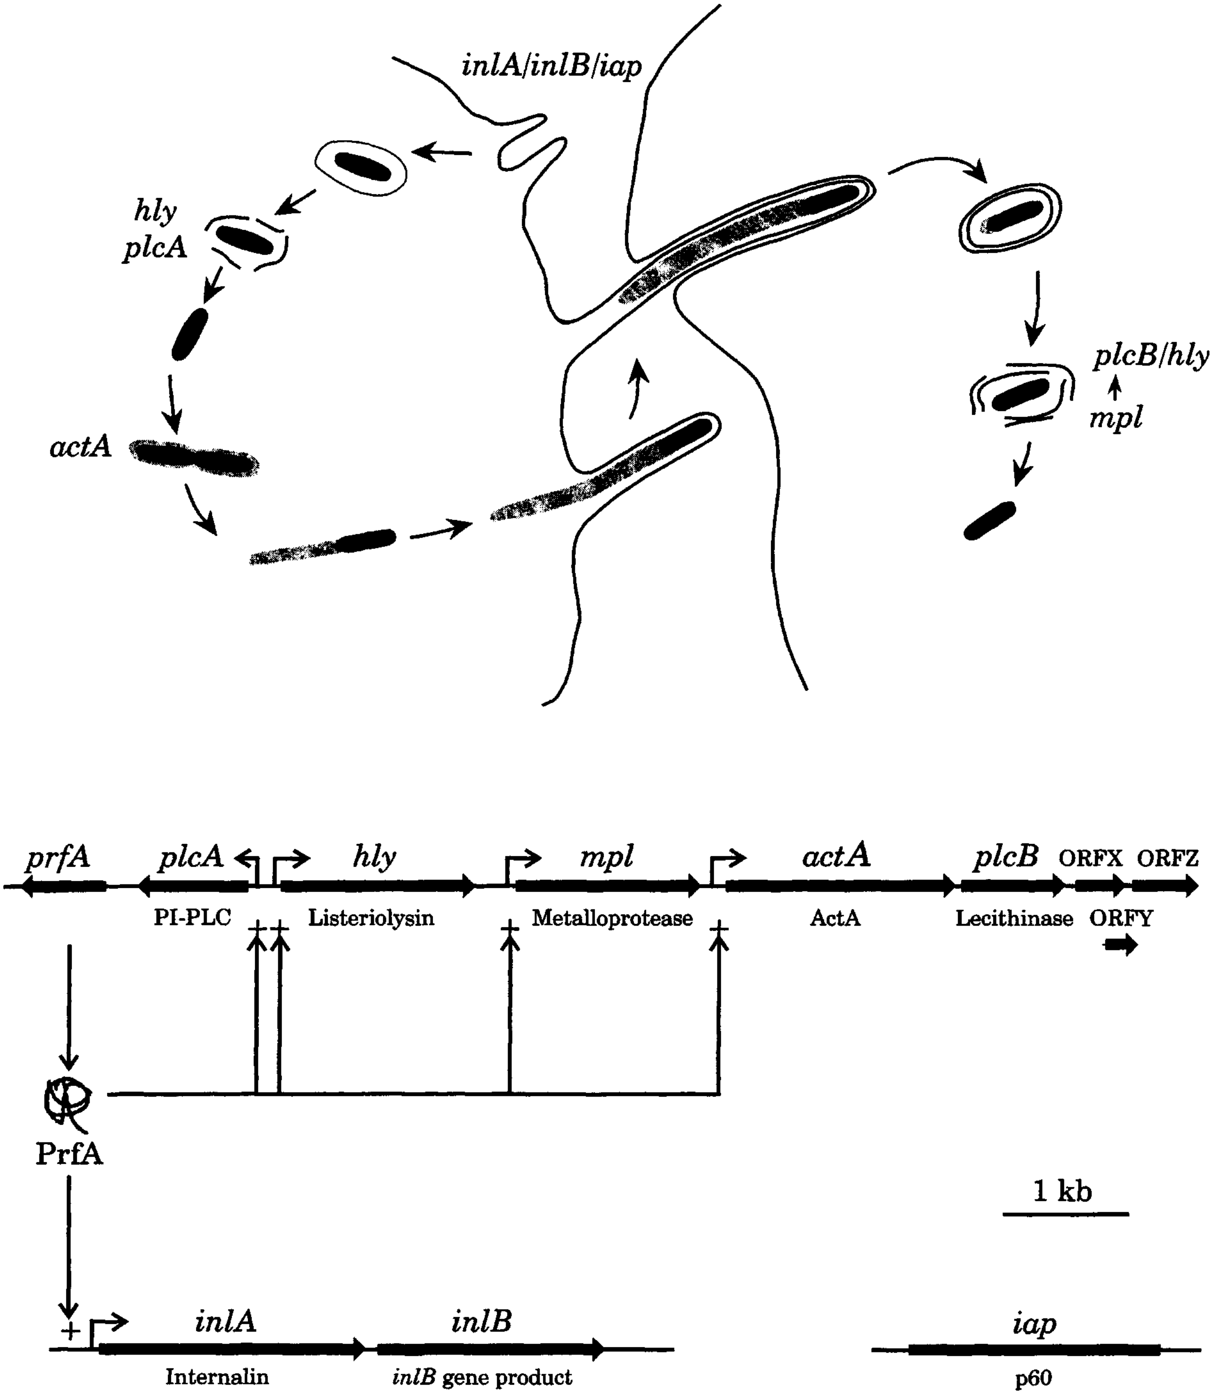

Figure 44–2 The Infectious Process and Virulence Factors of *Listeria monocytogenes*. A diagram of the infectious process is shown, together with the genes required at each step of the process. The arrangement of the various virulence factor genes on the chromosome is shown beneath, including the interaction of PrfA with its target sites. *Source:* Adapted with permission from S. Dramsi, C. Kocks, C. Forestier, and P. rophage cytoplasm.[40] Unlike other thiol-activated cytolysins that act extracellularly, LLO has a pH optimum of 5 and is able to exert its lytic activity within the acidic environment of the phagosome.[456]

PI-PLC is encoded by *plcA*, a gene upstream from *hly* in the *prfA* regulon (Figure 44–2).[297,352] PI-PLC is a 37-kDa phospholipase specific for PI and is active on a PI-glycan-anchored protein.[202] Transposon mutations in *plcA* result in a loss of virulence in mice, but this is probably due to a polar effect on the regulatory gene *prfA*, which is downstream from *plcA*.[66] The product of this gene plays a significant role in mediating escape of *L. monocytogenes* cells from phagosomes after internalization.[66,408]

For movement across the cell and into neighboring cells, *L. monocytogenes* appropriates the host cell actin machinery.[86,94,492,494] The ability to spread within host tissues by direct cell-to-cell spreading constitutes an essential feature of its virulence.[443] Three genes, *mpl*, *actA*, and *plcB*, have been implicated in this process.[113] These genes, together with three small ORFs downstream from *plcB*, form the lecithinase operon. ActA, encoded by *actA*, is a surface protein with an apparent molecular weight of 90 kDa and with a membrane anchor at its COOH-terminal end.[113,284] The amino-terminal end of ActA is critical for actin assembly and bacterial movement.[293,468] ActA conferred actin-based motility on the nonpathogen *L. innocua*.[285] ActA recruits the host cell actin to assemble continuously at one pole of the bacterial cell surface, forming an actin tail up to 5 μm long, which propels the bacterium across the cytoplasm, pushing on the host cell membrane and forming a protrusion, which can be ingested by an adjacent cell (Figure 44–2).[495,496]

Actin is the most abundant protein in the mammalian cytoplasm, existing either as ADP- and ATP-actin monomers or as filaments formed by head-to-tail polymerization of the asymmetric monomers. The first step in the nucleation process, which seems to be under ActA control,[173] involves the combination of three ATP-actin monomers to form an unstable trimer. This elongates in a polar action, by the addition of monomers more rapidly to the end of the asymmetric actin tail that is attached to the bacterium.[87] The host cell protein, profilin, binds to monomeric ADP-actin, distorting its structure and allowing the exchange of ATP for ADP,[283,493] thereby promoting actin filament assembly. Profilin is the only actin-regulatory protein that binds to polyproline. Each molecule of ActA bacterial protein contains four proline-rich sites that bind the host cell protein, vasodilator-stimulated phosphoprotein (VASP).[404,406] Each VASP monomer contains four polyproline-rich sites, each with the potential to bind profilin. Because VASP exists as a tetramer in the host cell, each ActA molecule can therefore attract up to 64 molecules of profilin, amplifying the ATP/ADP exchange in the promotion of actin filament assembly. The elongation of the filament is promoted, supplying the motive force for the migration of the bacterial cell through the cytoplasm.[76,468] A number of additional host cell proteins regulate the filament assembly, including filament-capping proteins, cross-linking, and bundling proteins.

On arrival at the plasma membrane of the host cell, the bacteria induce the formation of pseudopod-like membrane protrusions. Contact between these protrusions and the plasma membrane of adjacent cells results in the internalization of the protrusion containing a *L. monocytogenes* cell, which is now surrounded by a double layer of plasma membrane (Figure 44–2). Lysis of these vacuoles involves a broad-range lecithinase or phospholipase C (PLC), encoded by *plcB*.[189,420,469,507] PLC is a 29-kDa protein, synthesized as a precursor, which is then cleaved by a zinc metalloprotease,[409] which is encoded by the *mpl* gene.[112,354] LLO may also contribute to the lysis of the double membrane vacuole, though in LLO⁻ mutants, the broad-range PLC and the metalloprotease were sufficient for lysis in Henle 407 cells.[328]

There have been no reports of listerial virulence factors that have systemic effects, except for that of a cholera toxin-like protein encoded by a gene that has been sequenced.[183]

44.4.2 Regulation of Virulence Factors

Complementation analysis and studies of transposon or insertion mutants demonstrated that *prfA* is a pleiotropic activator of virulence gene expression.[122,353] It regulated a polycistron containing eight genes,[75,200] as well as the *inl* multigene family located elsewhere on the chromosome (Figure 44–2). PrfA, its gene product, is a 27-kDa protein that activates transcription from the *plcA, hly, mpl,* and *actA* promoters, as well as the *inlAB* promoter.[171] Activation was most efficient at the divergently transcribed *plcA* and *hly* promoters; the activation of *mpl* and *actA* was considerably weaker.[457] Transcription of *prfA* does not occur below 30° C.[298] PrfA shows similarity to the *E. coli* cAMP receptor protein and is a site-specific DNA-binding protein.[172]

Apparently, the PrfA protein acts through direct binding to specific sites in front of the respective gene promoters,[46] because on gel electrophoresis it retards the mobility of DNA fragments containing the 14 bp palindromic sequence located between the divergent *hly* and *plcA* promoters. Similar palindromic sequences are found in the –35 regions of *mpl*,[351] *actA*,[507] and the internalin locus promoters.[123] *InlA* and *inlB* are transcribed in their operon and individually by both PrfA-dependent and PrfA-independent mechanisms.[304]

The regulation of *prfA* expression is complex. The gene is not constitutive, as two peaks of *prfA* transcription occur during the growth cycle *in vitro*.[353] The first occurs in early exponential phase when *prfA* is cotranscribed with *plcA* from the 3' end of the *plcA* gene. The second occurs at the end of exponential growth, is monocistronic, and originates immediately 5' to the *prfA* gene. The primary promoter for the cotranscription of the *plc-prfA* operon is regulated by *prfA*; thus, *prfA* autoregulates its own synthesis.[172] Dual promoters have been demonstrated immediately upstream of *prfA* coding sequences.[170] *PrfA* was among five genes preferentially expressed when *L. monocytogenes* was in an intracellular environment in infected macrophages.[278]

44.4.3 Host Cell Protective Mechanisms

Although it was once thought that immunity to *L. monocytogenes* could be explained entirely by the generation of activated macrophages, it is now clear that the immune response to the organism encompasses both an innate and an acquired response.

Macrophages become activated in the defense of the mammalian host against intracellular listerial infections with the formation of reactive oxygen and nitrogen intermediates such as superoxide.[228] The bacterial enzyme, superoxide dismutase (SOD), converts superoxide into hydrogen peroxide, which is further metabolized by catalase, thus counteracting the defense mechanisms of activated macrophages. The SOD from *L. monocytogenes* has been sequenced and shows close similarity to Mn^{++}-containing SODs from other organisms.[54]

Acquired immunity to listerial infections is cellular in nature with antibodies playing no role because the bacteria never confront the humoral immune system. Immunity to *L. monocytogenes* is restricted largely to major histocompatibility complex class I antigens, with the processing of the antigens in the cytoplasmic environment, and their presentation to $CD8^+$ T cells.[407] Thus the organism must lyse the phagosome and enter the cytoplasm for the induction of immunity.

The question of the minimum infectious dose (MID) of *L. monocytogenes* for humans is a vexing one. There is some indication of strain dependency because many of the larger foodborne outbreaks have been due to serotype 4b. The immunological status of the host seems to be a critical factor because few cases of listeriosis are reported in adult, immunocompetent persons. Oral challenge of *Cynomologous* monkeys with 10^5, 10^7, and 10^9 *L. monocytogenes* showed that only those receiving 10^9 bacteria developed fever, septicemia, loss of appetite, irritability, and occasional diarrhea.[151] All listeriosis cases published from foodborne outbreaks where the implicated food has been identified were caused by foods containing ≥100 cfu *L. monocytogenes* g^{-1}.

44.5 INCIDENCE OF *L. MONOCYTOGENES* IN FOOD AND THE ENVIRONMENT

44.5.1 Dairy Products

Since dairy products were one of the first food groups reported to be involved in outbreaks of listeriosis, extensive surveys have been made of the incidence of *Listeria* on the farm and in food processing environments, as well as studies on the incidence, survival, and growth of the organism in dairy products. *L. monocytogenes* is endogenous to the farm environment, where it can be found in water, fecal material, soil, and cow's hair. The organism can be transmitted to cows via feeds such as improperly fermented silage, hay, and oatmeal as well as by straw and fecal contamination (Figure 44–1).[214,244,501] The relationship between silage feeding and animal listeriosis has been known for years.[210] The survival of the organism in silage depends on the complex interaction between dry matter, O_2 tension, grass, and microbiological quality. In general, the organism will survive and grow well in silage with an O_2 concentration of ≥ 1% and a pH > 5.0.[115,399,501] However, the organism has been found in silage ranging in pH from 3.8 to 5.2.[422] In addition, mastitis occurs in animals, with consequent chronic shedding of the organism for a number of years.[116,150] The organism has been recovered from mastitic animals at levels ranging from 10^3 to 10^4 cfu ml^{-1} of milk. There is a wide range in the reported incidence of the organism in raw milk (Table 44–5). In a large case-control study involving 128 dairy farms, factors associated with raw milk contamination by *L. monocytogenes* included poor quality silage, infrequent cleaning of the exercise area, poor cow cleanliness, insufficient lighting of milking barns and parlors, and incorrect disinfection of towels between milkings.[441] Samples obtained from factory silos or large processing centers have a much higher incidence of contamination than do bulk tank samples (Table 44–5). This is probably due to the pooling of contaminated milk samples. The levels of the organism in raw milk are usually less than 1 cfu ml^{-1}, but can range up to 62 cfu ml^{-1}.[158,383] Although O'Donnell[383] and Rea et al.[422] found a marked seasonal trend, with the highest incidence of *Listeria* in raw milk in the winter months when the cows were housed indoors, other investigators have found a higher incidence in the summer.[148,157] O'Donnell's work showed that as a percentage of total *Listeria* isolated, *L. monocytogenes* was the dominant species isolated during the summer months. The organism grows well in both raw and pasteurized milk, with reported generation times at 10° C of about 10 hours.[147,330]

Much evidence suggests that environmental contamination, in particular postprocessing contamination, is a major source of contamination of food (Figure 44–1). The organism is prevalent in the environment and on equipment in dairy processing operations.[67,77,279,411,412] Sites typically positive for *L. monocytogenes* include drains, conveyor belts, floor mats and foot baths, coolers, freezers, areas underneath equipment and associated with case washers, raw milk-associated areas, cheese-ripening rooms, and cheese washing brushes. A large study[411] of the incidence of *Listeria* in the environment of 30 dairy processing plants, either with or without an onsite dairy farm, found that 57.9% and 38.5%, respectively, of the sites tested were positive for *Listeria*. No one area appeared to be more highly contaminated than any other. The environment of a dairy operation can be more contaminated than the equipment within the same plant (ie, 6 of 21 plants testing positive for equipment versus 19 of 21 plants having positive environmental samples).[412] The authors suggested that even when the organism is present in the environment of a particular plant, this will not automatically lead to prolonged contamination of the equipment.[412]

44.5.2 Meat and Poultry Products

Contamination of meat products by *L. monocytogenes* can originate from the processing environment of the chilling or cutting room,[405,506] hands,[275] and equipment.[294] Additional major points of contamination include contact of cooked products with soiled surfaces, cross-contamination between raw and cooked channels, and the inadequacy of cleaning and disinfection procedures.[440] In a study that examined product and environmental contamination of six delicatessen plants in France, before disinfection transport belts, tables, gloves, hands, meat and jelly containers, and knives were the most highly contaminated, while after disinfection meat containers, knives, and caddies were the most highly contaminated.[440] In cattle and lamb, animal hides and pelts were more important sources of *Listeria* in the carcass than fecal contamination,[316] while in pigs, fecal contamination was the most important source of carcass contamination.[5]

L. monocytogenes can be isolated both at the abattoir[307,316] and at the retail level,[240a,294] and a wide variety of meats have been found to be contaminated with *L. monocytogenes* (Table 44–6).[142,261] The reported incidence of contamination varies greatly, due largely to methodology differences including such factors as the method used, sample size, the number of single colony isolates taken to confirm the presence of hemolytic colonies, and whether samples were purchased from retail or commercial outlets. Survey data show *L. monocytogenes* to be present in a wide variety of raw and ready-to-eat (RTE) meats (Table 44–6). As well as in North America and Europe, *L. monocytogenes* has been isolated from meat and meat products in South Africa,[513] Trinidad,[5] Japan,[438] China,[520] Malaysia,[13] and New Zealand.[405] Most of the observed contamination is on the surface; however, *L. monocytogenes* was found in the interior muscle cores of 5 of 110 total samples of beef, pork, and lamb roasts.[261] These organisms were probably present in muscle at the time of slaughter. Serotype 1 is the most frequent serotype found in meats worldwide.[142]

Poultry can become contaminated with *Listeria* either environmentally during production or from healthy carrier chickens in the processing plant.[18,186] Carcass gut contents, food handlers, contaminated surfaces (eg, "rubber fingers"), scald tank water, and contaminated equipment[126,190] have been implicated as sources of *Listeria*. A limited number of *Listeria*-contaminated poultry carcasses may contaminate a larger number of carcasses in the chilling water.[167] Contamination of turkey carcasses occurred after defeathering during either evisceration or chilling. Main sources of *L. monocytogenes* contamination were insufficiently cleaned equipment and the hands and gloves of workers in the final process areas.[81] Some strains of *L. monocytogenes* appear capable of adapting to certain niches in poultry plants, persisting for long periods of time (up to 1 year), and causing cross-contamination.[294]

Chicken can be heavily contaminated with *L. monocytogenes*, and the incidence of *L. monocytogenes* can range from 12% to 92% in raw broilers,[142,239,261,307] to 12% to 27% in cooked and RTE poultry products, respectively.[192,274,424] Franco et al.[167] found drumstick meat and skin to be the most contaminated of the poultry pieces examined, ie, 95% of samples contained *Listeria* spp. The authors concluded that drumsticks were responsible for a large amount of the contamination of chicken carcasses, that most contaminated areas were in the final stages of meat processing, and that work surfaces in contact with meat were an important source of *Listeria* spp. Both raw and cooked poultry products were the foods of greatest concern in terms of the incidence and levels of *L. monocytogenes*.[319,525] A cooked poultry product was found to contain 1,200 cfu g^{-1} of *Listeria*, while two cooked turkey products contained $>10^4$ cfu g^{-1} of *L. monocytogenes*.[319,525] Such numbers in cooked products might be due to undercooking or to contamination and multiplication after cooking. One would expect to see sporadic cases of listeriosis as the result of random occurrence of undercooking (Section 44.6.2).

Few studies have examined the serotype predominance in chickens, but it appears that, as for beef, serotype 1 is the most prevalent. Bailey et al.[18] examined the factors influencing colonization of broiler chickens with *L. monocytogenes*. Although *L. monocytogenes*, orally inoculated, does not colonize chickens as easily as do salmonellae or *Campylobacter jejuni*, younger birds were more susceptible to colonization than older birds, and there was a dose-related colonization response.

Most studies have found *L. monocytogenes* in meats initially at very low levels (<100 cfu g^{-1}). For example, the organism was present in wiener packages at levels of 0.34 to 2.3 MPN ml^{-1} of exudate.[519] Villari et al.[511] found levels of the organism to be highest in poultry, followed by pork and then beef. During quantitative analysis, however, most investigators do not include a resuscitation step. When a resuscitation step was used, the levels of *Listeria* spp. from meat and fish products were up to 2.5 logs

Table 44–6 Incidence of *Listeria monocytogenes* (*Lm*) in Meats

Meat Type (Country)	*Incidence of* Listeria *spp. (%)*	*Incidence of* Lm *(%)*	*Numbers*	*Comments*	*Reference*
Retail frankfurters (US)	9/93[a] (10)	7/93 (7.5)	0.34 to 2.3 MPN ml^{-1} of exudate	*Lm* found in 6 of 20 brands tested	519
Retail vacuum-packaged processed meats (Australia)	93/175 (53)	78/175 (44.6)	3.1–3.3 x 10^4 cfu g^{-1} [b]	corned beef most highly contaminated	208
Retail luncheon meat and pâtés (Spain)	30/96 (31)	21/96 (21.9)	83% of samples <10 cfu g^{-1}		290
Frankfurters and RTE sliced meats (Denmark)	ND[c]	38/304 (12.5) 41/304 (13.5)	99% of samples <100 cfu g^{-1}	4 x 10^3 cfu g^{-1} found in a frankfurter sausage at expiration date	416
Fresh ground beef, fresh pork meat, and sausages (Italy)	176/490 (35.9)	65/490 (13.3)	<100 (91.6–92.6%) 100–1000 (3.7–5.6%) 1000–2000 (2.8–3.7%)		83
Processed meats (US)	ND	294[d]/20,296 (1.4)	ND		329
RTE meats (Northern Ireland)	285/5020 (5.7)	ND	ND	undercooked chicken appeared to present the greatest risk	525

[d] Plants with positive *Lm*.

RTE, ready-to-eat

higher than without resuscitation, indicating the presence of large numbers of injured cells that were undetected in the absence of resuscitation.[459]

In addition to the sporadic cases of listeriosis involving meat products, there have been numerous recalls in the US, Canada, and the UK of meat products containing *L. monocytogenes*. The products recalled have included turkey franks, farm sausages, cooked ham, prepared hamburger sandwiches, hot dogs, chicken spread, vacuum-packaged sliced ham, sausage sandwiches, chicken, egg and ham salads, frozen heat-and-serve chili dog and chili and cheese dog sandwiches, and Cajun pork sausages. The total economic loss to the respective companies has run well into the millions of dollars.

Because of the widespread distribution of *L. monocytogenes* in and around meat processing plants, it is unlikely that *Listeria* can be eliminated from meat packing plant environments.[261,294,405] Proliferation of *L. monocytogenes* in food plant environments is promoted by high humidity and nutrient waste.[446] However, in some operations, meat carcasses can be prepared free of *L. monocytogenes*, and proper cleaning of processing equipment can largely prevent meat becoming contaminated with *Listeria*.[194,405]

44.5.3 Fish and Seafood

Water plays a major role in the cycle of infection by *Listeria*[107] and may be the original source of seafood contamination. There are a number of ways by which *Listeria* can enter into the water supply—fecal contamination from animals, release of sewage effluent, and runoff from agricultural land.[175] *L. monocytogenes* can be found mainly in freshwater and seawater from coastal areas.[26]

In a study of the incidence and sources of *L. monocytogenes* in cold-smoked salmon plants, the primary source of contamination was the surface of the fresh or frozen raw fish coming into the plant, and during the filleting, rinsing, and brining stages, the organism could be transferred to the exposed flesh.[128] As the product moved through the different processing areas, anything that came into contact with the exposed contaminated flesh (ie, personnel, equipment, work surfaces) was liable to become contaminated and then serve as a secondary source of contamination.[128] In a cold-smoked salmon slaughterhouse and processing plant, a low incidence of the organism was found in the slaughterhouse and in the slaughtered fish, but a high incidence was found in the smokehouse.[433] Molecular typing of isolates revealed that there was one predominant ET (ET-6) present in the smokehouse; this same ET was the only one recovered from the vacuum-packed (VP) smoked salmon.[433] Although it appeared that a reservoir of *L. monocytogenes* was established in the smokehouse, the original source of contamination was not identified (ie, strains isolated from seawater and fish were not ET-6). *L. monocytogenes* could be recovered from many sites in a raw shrimp processing plant from processing water, utensils, food handlers, floors, walls, doors, and drains.[102] The number of different strains recovered from shrimp in the processing area was high. Since there were many different sources of the organism in the shrimp processing plant, the authors concluded that the elimination of *L. monocytogenes* from the frozen finished product would be virtually impossible under the processing conditions existing in the plant. Of three Swiss rainbow trout fish farms and their affiliated smoking plants, one plant was much more highly contaminated than the other two, both in the plant environment and in the product.[255] This was attributed to the fact that this plant did not have a regular cleaning and disinfection schedule and the fish had not been denied feed before slaughter; the practice of denying feeding is designed to reduce fecal contamination in the slaughter area.

A number of studies examined the incidence of *L. monocytogenes* in seafood with the prevalence of the organism in fresh and frozen fish, processed seafood, shrimp, and shellfish being 0% to 50%, 0% to 26%, 0% to 20%, and 0% to 7.5%, respectively.[26] The incidence of *L. monocytogenes* in tropical fish and fish products, including dried-salted fish, appears to be low, although only limited data are available. The overall incidence of *L. monocytogenes* in RTE cold-smoked salmon and cooked fish products has been estimated at 6% to 36%.[26] Of 377 samples of smoked and marinated fish, 47 were positive for *L. monocytogenes*[253] and of 100 smoked samples, 24% were positive for the organism. Compared with cold-smoking, which has little or no effect on *L. monocytogenes*, hot-smoking fish can lead to up to a 6-log reduction in numbers of the organism.[254] However, hot-smoking fish can lead to higher levels of *L. monocytogenes* on the product after storage than cold-smoking because of the elimination of the background microflora. Although the incidence in seafoods can be fairly high (Table 44–7), usually very low numbers (<100 cfu g^{-1}) of the organism are found.[128,137,421] A study in the UK found *L.*

monocytogenes in 128 (3%) of 4,435 seafood samples, but in only 8 of these were levels higher than 10^2 cfu g^{-1}.[343] A significant association was found between the presence of *Listeria* and high viable counts. The seafoods with the highest incidence (7%) of contamination with the organism were smoked fish and fish pâtés.

Fish products, nevertheless, have been involved in both sporadic cases and outbreaks of listeriosis (Table 44–8). In addition, many fish products in North America including frozen cooked shrimp, canned frozen, fresh and imitation crab meat, smoked salmon, imitation scallops, frozen canned lobster, and surimi products have been found to be contaminated with *L. monocytogenes* and been recalled from the market.

44.5.4 Vegetables

L. monocytogenes is widely distributed on vegetation and probably contaminates it via many routes including soil, water, animal manure, decaying vegetation, and sewage effluents (see Figure 44–1). Although many types of vegetables have been analyzed for *L. monocytogenes*, only potatoes and radishes appear to be contaminated on a regular basis.[149,226,464] On fresh-cut vegetables, the incidence of the organism varies from 0 to 19%.[70] Low levels of *L. monocytogenes* (<200 cfu g^{-1}) have been found in positive samples.[508] As with most foods, serotype 1 appears to be the predominant serovar.

44.6 EPIDEMIOLOGY

44.6.1 Food-Related Outbreaks

The vehicles of infection by *L. monocytogenes* in both sporadic and epidemic listeriosis were not proven until the early 1980s, although transmission in milk was suspected and direct transmission from infected animals to farm workers and veterinarians producing cutaneous lesions was well documented. However, an outbreak with 41 cases (34 perinatal, 7 adult) (Table 44–8) occurred in the Maritime Provinces of Canada between March and September 1981.[444] Of the 34 perinatal cases, there were 9 stillbirths, 23 live births of ill infants with a subsequent 27% mortality rate, and 2 live births of well infants. The adult mortality rate was 28.6%. During the epidemiological studies, an elderly individual was admitted to the hospital for what turned out to be a case of listeriosis. Because this was a frugal individual, leftovers remained in his refrigerator. Examination of all suspect foods revealed the presence of *L. monocytogenes* type 4b, the epidemic strain, in a packaged coleslaw mix that contained no dressing. Coleslaw was then included as a food item in the second food questionnaire, and the rest of the puzzle solved. The coleslaw mix had been prepared by a regional manufacturer, and distribution was confined to the Maritime Provinces. Environmental cultures taken at the implicated plant failed to reveal *L. monocytogenes*. A review of the sources of

[a] For two of these five deaths, an underlying disease, not listeriosis, was apparently the cause of death.
[b] Foods only epidemiologically linked.
[c] Outcome only known for 252 cases.
[d] Only 314 patients categorized.
[e] Includes two sets of twins.
[f] Outbreak was centered in Wisconsin.
[g] Spontaneous abortion.
[h] Not known if death due to listeriosis or leukemia.

raw vegetables for the plant identified a farmer who raised cabbage and kept a flock of sheep, of whom two had died of listeriosis, one in 1979 and one in March 1981. The cabbage was grown in fields fertilized by both composted and raw manure from this flock. Following the cabbage harvest each October, the crop was stored in a large cold-storage shed. Because *L. monocytogenes* is able to grow at low temperatures, the period of cold storage of the cabbages and the refrigeration of the coleslaw mix may have acted as a period of selective enrichment for the organism.

In the summer of 1983, an outbreak of listeriosis associated with *L. monocytogenes* type 4b occurred in Massachusetts (Table 44–8).[161] Of the 42 adult and 7 perinatal cases, 14 (29%) died. Case-control studies showed that the outbreak was strongly associated with drinking a specific brand of pasteurized milk. The case for an association with milk was strengthened by linkage of a specific phage type with the milk-associated disease. The milk associated with the outbreak came from a group of farms where bovine listeriosis was known to have occurred at the time of the outbreak. *L. monocytogenes* was isolated from raw milk at these farms. There was no evidence for improper pasteurization procedures at the plant, and this raised the question as to whether *L. monocytogenes* survived the pasteurization and whether its intracellular location gave it added protection.

The outbreak that raised listeriosis to a higher level of concern among food manufacturers and regulatory agencies occurred in California from January to August 1985 (Table 44–8).[306] Of the 142 reported cases, 93 were perinatal and 49 were adult, with 48 deaths (34% mortality rate): 30 fetuses and newborn infants and 18 nonpregnant adults. Among the 49 adult cases, 48 were immunosuppressed, elderly, or had a severe chronic illness. Case-control studies implicated Mexican-style soft cheese of a certain brand produced in plant A. The presence of *L. monocytogenes* type 4b, of the epidemic phage type, was confirmed in this cheese. Environmental samples taken from the plant producing the implicated cheese were positive for the epidemic phage-type organism. Although the pasteurizer was in good operational order, 9 of 80 cheese samples tested positive for phosphatase, suggesting a bypass of the pasteurizer (several occasions were documented of delivery of more raw milk than could be handled by the pasteurizer) or the introduction of raw milk after pasteurization. The factory was closed and the cheese of the implicated brand was recalled. *Listeria* spp. were not found in raw milk samples from the 27 dairy farms supplying the cheese plant; however, food products (Mexican-style sour cream and cottage cheese byproducts) from plant B, which was one of the major suppliers of raw milk to plant A, were also contaminated with the epidemic phage type. This is the first recorded listeriosis outbreak in which the food causing the epidemic was identified and recalled during the outbreak.

Another outbreak due to the consumption of soft cheese[41] occurred in western Switzerland (canton de Vaud). During 1983 to 1987, 122 listeriosis cases with 31 deaths were recorded (Table 44–8). More than 85% of the strains isolated during the epidemic period were of a similar serotype (4b) and phage type. Initially, a source of infection or route of spread could not be found; however, following the Jalisco cheese outbreak, an extensive survey of dairy products for *Listeria* spp. was carried out in Switzerland. When the isolates from this survey were sero- and phage-typed, only those recovered from the surface of Vacherin Mont d'Or soft cheese were identical to the outbreak strains. A follow-up investigation of the entire Vacherin production also turned up strains of a similar phage and serotype. Clinical cases were observed mainly during the winter period because the cheese was produced exclusively during the winter season and eaten in the area where the cases occurred. In late November 1987, all products were recalled from the market. This was an effective control procedure, in that the number of new cases in the area dropped substantially and no case due to an epidemic strain was recorded in 1988.[41] An examination of the 57 nonperinatal cases showed that there was an unusually high percentage (79%) of cases of CNS listeriosis in relatively young, previously healthy adults, with neurological sequelae developing in 30% of survivors, and mortality was positively associated with increased age and a clinical presentation of meningoencephalitis.[63]

A routine investigation of foods from a patient's refrigerator after a listeriosis case in the UK in 1989 led to finding a pâté sample that contained high levels of *L. monocytogenes*. This finding led to surveys, government health warnings to high-risk groups about pâté consumption, and a nationwide study to examine the relationship between human listeriosis and pâté consumption. During the 1989 survey, pâté samples from a single plant were more frequently contaminated with *L. monocytogenes* and at higher levels than those of other producers.[345] *L. monocytogenes* serotype 4b (phage type 6,7) and serotype 4b(X) accounted for 96% (48 of 50) of all isolates from the manufacturer's pâté, compared with 19% (6 of 31) of those from other producers in the 1989 survey, 4% (1 of 25) in the 1990 pâté survey, and rarely from other foods. The upsurge in cases of human listeriosis between 1987 and 1989 in the UK was due to these two serotypes, which accounted for 30% to 54% of the annual totals of cases. The two strains were much less common both before 1987 and after mid-1989.[345] Patients infected with the epidemic strains were significantly more likely to have eaten pâté recently than those affected by other strains. Government health warnings and suspensions of sale of pâté from the manufacturer involved were followed by a rapid decrease in the overall reported number of listeriosis cases, especially those due to the two epidemic serotypes. This provided circumstantial evidence that the UK outbreak observed was due to contaminated pâté from a single manufacturer. Two other outbreaks in France and Australia have also been linked to the consumption of contaminated pâté (Table 44–8).

A very large outbreak of foodborne listeriosis, linked by a case-control study and characterization of food isolates to the consumption of pork tongue in jelly, occurred in France in 1992. A total of 279 people were involved, with 92 cases involving pregnant women or neonates and 22 pregnancies ending in spontaneous abortion.[205] Of the 73 infants born, 7 died (9.6% fatality rate). In the other 187 cases (5 infants and 182 adults), 61% had a known pre-existing condition. The investigation was complicated by the fact that cases were spread across 79 departments within metropolitan France. Unfortunately, because of rapid consumption of product, there was no remaining pork tongue in jelly found in any of the patients' refrigerators.[252] However, the epidemic strain was isolated from 220 food products including delicatessen products (135), cheeses (40), meat and meat products (31), milk (1), other foods (13), and environmental samples (40). Delicatessen items that were contaminated included products in jelly, various hams and pâtés, and rillettes and sausages. Further illustrating the complexity of this investigation, most of these latter products were sampled in at least 30 retail stores. It is also apparent from this outbreak that cross-contamination of deli-style meats at the retail level occurred frequently and was responsible for causing additional cases of listeriosis. Among patients who did not eat the implicated food (pork tongue in jelly brand A), listeriosis was associated with the consumption of foods handled in the same stores where pork tongue brand A was sold.[252]

Another small outbreak that occurred in France in 1995 (Table 44–8) highlights the danger of eating cheese made from raw milk, especially for high-risk groups. In this outbreak, out of 20 cases, 11 perinatal cases occurred, resulting in 4 premature births, 2 spontaneous abortions, and 2 stillbirths.[206]

It is not known how many cases of foodborne listeriosis occur in which only a mild upper GI-type illness is seen, but the numbers may be substantial. In spite of the fact that mild cases of listeriosis are difficult to detect, there have been a number of outbreaks where, in the majority of cases, only mild symptoms were observed. The foods involved have been as diverse as shrimp,[426] chocolate milk,[413] and rice salad.[439]

In a Philadelphia outbreak,[451] multiple serotypes (4b, 1/2a, 1/2b, 3b) and isoenzyme types (11) were involved, and *L. monocytogenes* was not isolated from any of the foods eaten by the patients. Because of all these factors, and the high rate of enteric symptoms experienced by the patients, it was hypothesized that an infecting organism (bacteria and/or virus) may have precipitated the multiplication of *Listeria* present in the gut.[451] The hypothesis that individuals colonized with *L. monocytogenes* may develop GI infection after infection with another pathogen gained some support when shortly after an episode of shigellosis due to contaminated water, a previously healthy 57-year-old farmer was severely infected by listeriosis.[311]

44.6.2 Sporadic Foodborne Cases

The foods associated with sporadic cases of listeriosis include meats and poultry products (turkey frankfurters, chicken, sausages), dairy products (cheese, ice cream, raw milk, and human breast milk), vegetable products (pickled olives, mushrooms, vegetable rennet, alfalfa tablets), and seafood (smoked cod roe, fish).[74,142,341]

Several of the cases provided some interesting background information. In a case involving chicken nuggets,[265] the son of the mother involved was also affected by a mild, brief GI illness. Culture of the son's stools yielded several serotypes of *L. monocytogenes*, one of which was the same as that isolated from the mother (1/2a).

In a sporadic illness involving whey cheese,[15] a follow-up study[344] suggested that many people in the UK were likely to have ingested this contaminated cheese. Cheese samples from the incriminated plant frequently were contaminated with high numbers of *L. monocytogenes* ($>10^5$ cfu g^{-1}); however, phage-typing data showed that only 3% of the reported listeriosis cases occurring in Britain in 1987–1988 belonged to this phage type. Thus, many people may have been exposed to doses of *L. monocytogenes* in excess of 10^5 cfu g^{-1} without becoming seriously ill.

A sporadic listeriosis case in which turkey frankfurters were implicated was the first well-documented case involving a meat product.[23] The patient heated the product in a microwave oven for 45 to 60 seconds on high power before eating, suggesting that this microwave treatment was not sufficient to inactivate any *Listeria* present. As a result of this case, 600,000 pounds of turkey hot dogs were recalled by the hot dog manufacturer.[9] A case involving human breast milk was interesting in that some of the incriminated milk had been given to three Doberman puppies, all of whom became sick with vomiting, diarrhea, and blood in the stools. *L. monocytogenes* was isolated from the stools of one of the two surviving dogs.[482]

A retrospective study conducted in 1986–1987 of 154 listeriosis patients in six regions in the US found that sporadic cases were significantly more likely than controls to have eaten either uncooked hot dogs or chicken meat that was still pink.[450] A two-part follow-up study to examine the role of foods in sporadic listeriosis was conducted in 1988–1990 using a multistate population of 18 million people.[402,448] A case-control study found that soft cheeses (ie, Mexican-style cheese or feta) and foods from store delicatessen counters were significantly associated with an increased risk of listeriosis.[448] Undercooked chicken was also found to be a risk factor, but only in the most immunocompromised (ie, those affected by cancer, AIDS, organ transplants, immunosuppressive therapy) patients. This is in line with current theories that the MID for high-risk individuals is lower than that for the normal population. The second part of the study identified specific factors that would be likely to lead to an episode of sporadic listeriosis.[402] These included foods that contain high levels of *L. monocytogenes*, foods containing serotype 4b, and RTE foods. In this study, *L. monocytogenes* was found in the contents of two-thirds of the 123 refrigerators and in 11% of the total foods examined. The authors suggested that the majority of human listeriosis cases are foodborne.

There have been other outbreaks of listeriosis in which no foods have been implicated.[142] One of these outbreaks, which involved nine ill infants (4 to 8 days old) born after the delivery of an infant with early onset listeriosis, occurred in Costa Rica in 1989.[447] The newborn infants were bathed liberally over the entire body surface with mineral oil, which would come in contact with the baby's mouth, nose, and mucous membranes. The mineral oil, which was kept open on a cart, may have become contaminated through the splashing of contaminated amniotic fluid from the index case or via contaminated hands. Subsequent outbreak-associated cases were bathed with oil from the same container. Although many infants were exposed to the oil, invasive disease may have developed only in those babies who had aspirated the oil, with general anesthesia possibly increasing the risk of aspiration.[447] This hypothesis was partially supported by the finding of lipid-laden macrophages consistent with oil aspiration and traces of *L. monocytogenes* DNA in lung tissue from the one infant who died. As a result of the outbreak, the use of mineral oil for bathing neonates in Costa Rica was discontinued.

44.7 FACTORS AFFECTING GROWTH AND SURVIVAL, PARTICULARLY IN FOODS

44.7.1 Growth in Foods

L. monocytogenes can survive the manufacturing and ripening of many different types of cheeses[142] but tends to survive and grow best in soft and semi-soft cheeses, where levels as high as 10^5 and 10^7 cfu g^{-1} have been reported.[308,504] With soft cheese, the contamination is mainly localized on the rind surface.[17,435] This phenomenon is a result of the increased pH and proteolysis at the cheese surface due to the mold ripening process. During cheese manufacture, a highly significant correlation ($P < 0.005$) exists between *Listeria* growth, pH values > 5.5, and the absence of starter cultures.[188] Of 24 different types of cheese examined, ricotta and cottage cheese were the best and worst substrates for growth, respectively. Although *L. monocytogenes* was able to grow in 36.7% of the cheeses examined, there were a number of cheeses that caused gradual death of the organism at all temperatures (4° C, 8° C, and 30° C). Even though there was temperature-dependent growth of *L. monocytogenes* on a number of soft cheeses such as Brie and Camembert, little if any growth was observed in blue and white Stilton, Mycella, Chaume, and full-fat soft cheese with garlic and herbs stored at 3° C to 10° C.[17] Of 358 samples of various cheeses tested over a 2-year period, Mozzarella was the most contaminated (16%), followed by ricotta (9.1%) and gorgonzola (9%).[414] The incidence of *L. monocytogenes* in soft and semi-soft cheeses ranges from 0.5% to 15%.[142,308] A recent study of imported soft and semi-soft cheeses found that cheeses made from raw milk were much more frequently contaminated (42%) than cheeses made from heat-treated milk (2%).[308] In contrast, other studies have shown virtually no difference in the incidence of *L. monocytogenes* in cheeses made from raw or pasteurized milk.[52] The incidence of the organism in the final product will depend greatly on the amount of handling the cheese receives during manufacture. As compared with other bacteria, *L. monocytogenes* is a hardy microorganism that can survive for long periods in hard or semi-hard cheeses, or cheeses containing high levels of salt. As examples, *L. monocytogenes* was the only one of nine species of bacteria to survive the manufacture and ripening of Swiss semi-hard cheese[16] and survived much better in reduced-fat Cheddar-like cheese than did two species in the genus *Salmonella*.[348] The organism grew in white brined cheeses containing 10% and 16% NaCl and in white pickled cheese containing 8% NaCl.[1,271] Both Canadian and US requirements specify that hard cheeses made from raw milk should be maintained for at least 60 days at a temperature not less than 2° C. However, it is known that the organism can survive in some hard cheeses well past the 60-day hold period.[16,135,442]

Growth of *L. monocytogenes* on meats is highly dependent on the temperature of the meat, pH, type of tissue, and the type and amount of background microflora present. Glass and Doyle[198] found that the organism grew well on those meat products with a pH value near or above 6.0, while on meats near or below pH 5.0, the organism grew poorly or not at all. Poultry supported the growth of *L. monocytogenes* better than other meats, and roast beef, summer sausage, and hot dogs supported it the least. For roast beef, summer sausage, and hot dogs, the inhibitory factors appeared to be pH, combined pH and a_w, and liquid smoke, respectively.[198] *L. monocytogenes* also grew better at 0° C on vacuum-packaged beef of pH 6.0 than on meat of pH 5.6.[207] Regardless of storage temperature or pH, *L. monocytogenes* grew to higher levels on fat than on lean meat, probably as a result of a much shorter lag phase.[207] In contrast, other workers have found similar growth patterns of *L. monocytogenes* on both lean and fat beef tissue, with slightly longer lag periods occurring with the fatty tissue.[104]

L. monocytogenes can also grow in sausages,[417] on various types of wieners,[338] on VP and aerobic cooked beef,[240a] and on VP processed meats (corned beef, ham, and salami). High residual nitrite or lowered a_w reduced growth of *L. monocytogenes* on VP sliced corned beef and ham, particularly when stored at 0° C to 5° C;[208] *L. monocytogenes* grew faster on corned beef at pH $\approx$ 6.2, an a_w of 0.97, and with <5ppm NO_3 than on ham with a pH value of 6.6, an a_w of 0.97, and with 170 ppm NO_3. At 15° C, growth rates of *L. monocytogenes* and the background microflora, mainly lactic acid bacteria, were similar; at 5° C, *L. monocytogenes* grew at only one-third the rate of the lactic acid bacteria. The organism is also capable of growing on VP fresh ground beef at 4° C; however, the growth was slow, being more rapid at pH >6.0 and dependent on strain.[22] *L. monocytogenes* also was capable of growing well on liver pâté stored at 4° C and 10° C, and temperature was the only factor of several examined that exerted an effect on the growth rate.[154]

Conflicting results have been obtained on the effects of vacuum packaging of meats on the growth of *L. monocytogenes*. The organism grew equally well on VP and air-stored beef[104] but grew at a slower rate on VP chicken breasts than on film-wrapped samples.[72] *L. monocytogenes* was capable of growth on VP meat stored at 0° C, 2° C, 5° C, and 10° C; however, on high-pH beef packaged under 100% CO_2, it did not grow below 5° C.[193] The growth and survival of *L. monocytogenes* on meat stored under different gas atmospheres has recently been reviewed.[182] There have been conflicting reports on the ability of the organism to grow at high CO_2 levels, mainly because of the influence of factors such as pH, temperature, and microbial competition. Growth of *L. monocytogenes* at 4° C to 5° C has been observed on lamb and turkey roll at CO_2 levels of 50%,[144,382] whereas the organism was unable to grow at 6° C on chicken packaged under 30% CO_2 or at 4° C in an atmosphere of 75% CO_2.[219,526] However, adding 5% oxygen to the latter atmosphere resulted in growth of the organism. One can conclude that in most cases, *L. monocytogenes* will be able to grow in levels of CO_2 up to 50%. Growth of the organism in concentrations higher than this will depend mainly on the interplay between the gas atmosphere, pH, temperature, and microbial competition.

Most investigators studying the fate of *L. monocytogenes* in fermented sausages have found at least a 100-fold reduction in the organism during manufacture.[30,199,499] An exception was beaker sausage prepared without starter culture and held at 32.2° C for 16 hours, where the organism increased in numbers approximately 100-fold.[199] In contrast, no growth and a slight decrease of *L. monocytogenes* occurred in summer sausage made without starter culture.[30] These different observations most probably result from physical and chemical differences between sausages (ie, pH, a_w, salt and nitrate levels, background flora). In general, the organism appears capable of survival on meat regardless of treatment; freezing, surface dehydration, and simulated spray chilling do not appear to affect the survival of the organism on meat adversely.[104,261,272]

The organism is able to grow on a wide variety of seafoods such as smoked salmon,[216,240,432] crawfish,[120] cooked blue crab,[421] cold-smoked cod fillets,[108] cooked shrimp and lobster meat,[137] and smoked trout.[254] In the latter study, $>10^7$ *L. monocytogenes* g^{-1} were found on hot-smoked fish that had been inoculated with 3.1 to 4.5×10^1 MPN g^{-1} after smoking, and then stored at 8° C to 10° C for up to 20 days. No growth of the organism was seen, however, in products stored at 4° C. This re-emphasizes two important points for the control of *L. monocytogenes* in all RTE foods, ie, the prevention of postprocessing contamination and the storage of products at as low a temperature as possible throughout the food chain. In challenge studies with the organism on seafood or on other foods, the initial inoculum needs to be considered. Very low levels (≤ 10 cfu g^{-1}) of *L. monocytogenes* may fail to initiate growth at low temperatures.[108,137,398] Since most fish products naturally contain low levels of the organism, the organism would not be expected to grow to high levels on seafoods unless the product is temperature-abused. This may explain the small number of listeriosis cases linked to seafoods (Table 44–8).

There have been relatively few studies examining the growth of *L. monocytogenes* on whole or fresh-cut vegetables. *L. monocytogenes* was able to grow on shredded lettuce stored at 5° C, 12° C, and 25° C, although the increase was only about 1 log after 14 days at 5° C or 25° C, and about 3 logs after 14 days at 12° C.[477] In several trials, the organism did not grow or had died off after 14 days. The variation in results could not be fully explained, but was partially attributable to differences of pH and surface moisture, or competition from the bacterial flora. Carlin and Nguyen-the[70] found that, except for lamb's lettuce, *L. monocytogenes* grew on a variety of inoculated green leafy vegetables. No explanations could be found for the lack of growth on lamb's lettuce. Various salads left at 4° C for 4 days supported growth of *L. monocytogenes* (roughly 2-fold increase), indicating that the organism can survive and multiply during storage of refrigerated preprepared salads.[464] After an initial decrease in numbers, *L. innocua* grew on freshly shredded white cabbage treated with citric acid and sodium erythrobate and stored at 11° C for 21 days.[389] The increase in numbers of this organism was less for cabbage packaged in film with the highest oxygen transmission rate, implying that in some cases the aerobic micoflora can compete successfully with *Listeria* spp. Although *L. monocytogenes* was unable to grow on air-stored chicory endive stored at 6.5° C, it did grow on VP product stored at the same temperature;[14] mung-bean sprouts did not support the growth of the organism under either atmosphere. On minimally processed fresh endive, *L. monocytogenes* grew at all temperatures tested, with the greatest increase in numbers occurring on leaves that had undergone extensive spoilage and contained the greatest numbers of aerobic bacteria.[71] Growth rates of the organism (Table 44–10) were similar to those of the aerobic spoilage flora at 10° C and 20° C, but slower at 3° C and 6° C.

L. monocytogenes grew well at 15° C on fresh vegetables stored in air or controlled atmosphere (CA) (O_2:H_2:CO_2, 11% to 18%:79%:3% to 10%), increasing by about 4 logs within 6 days on asparagus, broccoli, and cauliflower.[29] At 4° C, however, it increased by only about 1 log on asparagus after 14 days, and decreased by about 0.5 logs after 14 days on broccoli and cauliflower. The observation that CA storage did not influence the rate of growth of *L. monocytogenes* is significant, since the storage life of the vegetables was considerably increased by the CA treatment. For vegetables on which the organism is capable of growing at 4° C (eg, asparagus), the increased shelf-life of the products allows extra time for *L. monocytogenes* to grow to significantly higher levels.

L. monocytogenes does not appear to be able to grow well on carrots unless the carrots are cooked.[33] Indeed, an anti-*Listeria* effect has been observed, with raw carrots stored at 5° C or 15° C spoiling before *L. monocytogenes* could grow. Broth-culture medium containing as little as 1% raw carrot juice substantially inhibited the growth of the organism, compared with the control. Oxygen appears necessary for the antilisterial activity of carrot, and thus reactive oxygen species may be involved. However, many free radical scavengers tested did not reduce the antilisterial effect.[370] The antilisterial effect of carrot juice was greatest in the pH range 5.0 to 6.4 and at low temperatures; NaCl levels up to 5% were protective.[36] In an examination of the possible inhibitory effects of carrot juice on *L. monocytogenes* on foods, treatment of lettuce with carrot juice levels of 20% or 50% caused significant reductions of the organism during storage at 5° C, retarded growth at 12° C, and was without effect at 20° C.[34] Carrot juice had little or no inhibitory effect on the growth of *L. monocytogenes* on Brie cheese or frankfurter homogenates.

44.7.2 The Effect of pH, Water Activity, and Temperature

The limiting parameters for growth of *L. monocytogenes* with respect to pH, a_w, temperature, and gas atmosphere can be seen in Table 44–9. The temperature range for growth is between –0.4° C and 50° C, with the optimum temperature being 25° C to 30° C.[263,515] The organism grows slowly on foods at refrigeration temperatures, with generation times ranging from 22 to 61 hours (Table 44–10); however, on foods that are temperature abused at 10° C, generation times of 10 to 13 hours usually are observed. Various predictive models are currently available that describe the growth of the organism under a wide range of different conditions.[524]

The rate of inactivation of the organism is dependent on pH, the acidulant, and its concentration. There have been a number of studies assessing the relative antimicrobial effects of organic acids such as citric, lactic, and acetic acids.[58,59,248,533] Recognizing the difficulty in comparing results because of differences in methodology, extrinsic parameters, and bacterial strains, discrepancies exist regarding the relative antimicrobial activity of various acids. For example, based either on an equivalent pH or an equimolar basis, the relative activity has been reported as acetic > lactic > citric.[7,248,533] Other investigators, however, have found the relative order to be citric ≥ lactic ≥ acetic acid, when expressed on the basis of molar concentration of undissociated acid.[58,533] To complicate matters further, organic acids such as citric acid can actually be protective at low (0.1 to 0.5%) levels.[58]

44.7.3 The Effect of Inhibitors

Antibacterial compounds that are either present naturally in food or that can be added to it[138] and inhibit *L. monocytogenes* in broth include monolaurin,[385] high molecular weight sodium polyphosphates,[534] and lysozyme either alone[260] or in combination with EDTA or apo-lactoferrin.[397] Compounds found to be effective in foods include sodium diacetate in turkey slurries;[445] sodium lactate in cooked beef,[358] liver, and bologna-type sausages;[417,458] trisodium phosphate on sliced beef tissue;[105] and monolaurin and lactic acid in crawfish tail meat homogenate.[386] The incorporation of organic acids in alginate gels to enhance antimicrobial effects increased the inhibition of *L. monocytogenes* resident on beef tissue.[461,463]

The effect of antibacterial compounds in foods, however, depends on the composition of the food and on temperature, pH, a_w, and interaction with other hurdles. For example, minerals or mineral-as-

sociated components (eg, Ca^{2+}, Mg^{2+}) protected *L. monocytogenes* from inactivation by lysozyme and heat in milk.[276] No simple relationship was found between the listericidal nature of various marinades and the presence or absence of green shell mussels.[55] The antibacterial action of mint essential oil against *L. monocytogenes* in various model foods was dependent on the oil concentration, food type, pH, food composition, and storage temperature.[488]

Several general reviews have been published on the activity of starter culture bacteria and/or their bacteriocins against *L. monocytogenes*,[235,249,365] and more specific ones on mode of action,[2] potential use in meat[346] and dairy products,[196] bacteriocins produced by *Leuconostoc*,[224] and regulatory considerations.[160] Specific examples of the use of lactic acid bacteria or their bacteriocins are shown in Table 44–11. Some of the main issues are discussed in Chapter 12.

44.7.4 The Effect of Heat Treatment on Survival

The outbreak of listeriosis in Massachusetts in 1983, which was associated with the consumption of pasteurized milk, raised the question of the heat resistance of *L. monocytogenes*. In studies with *L. monocytogenes* (Scott A) suspended in raw milk and heated in sealed glass tubes, *D*-values of 19.9, 3.0, and 0.9 seconds at 53.3° C, 68.9° C, and 71.7° C, respectively, were obtained, giving a *z* value of 6.3° C.[50] It was concluded that the organism would not survive 71.7° C for 15 seconds, which are the conditions for high-temperature, short-time (HTST) pasteurization. Doyle et al.[121] infected four cows with *L. monocytogenes* (Scott A) and performed pasteurization trials on the milk obtained from these cows, which contained the organism within polymorphonuclear leukocytes. *L. monocytogenes* cells were recovered from six of nine trials in which the milk was heated from 71.7° C to 73.9° C, but were not recovered from milk that was heated from 76.4° C to 77.8° C. Initial levels of the organism in sonicated or homogenized milk ranged from 1.0×10^2 to 2.6×10^4 cfu ml^{-1}. They suggested that the discrepancy between this result, and that of Bradshaw et al.[50] was mainly due to the intracellular location of the bacteria. An extensive study involving sterile whole milk, in which *L. monocytogenes* cells were either freely suspended or located within bovine milk phagocytes, showed that the intracellular position of the organism did not significantly increase thermal resistance.[64] However, they did demonstrate that the HTST conditions did not provide an ad-

equate *D* process, as the predicted $D_{71.7° C}$ value for intracellular slug-flow heat exchange studies was 4.1 seconds. This suggested a possibly unsafe 3.7 *D* kill for a minimum (71.7° C; 15 seconds) commercial pasteurization, whether the organism was located extra- or intracellularly. In a later report, Garayzabal et al.[181] showed that although *L. monocytogenes* was not isolated from inoculated raw milk that had been treated in a pilot plant-size pasteurizer at temperatures ranging from 69° C to 73° C for 15 seconds if the isolation was attempted immediately after the thermal treatment, it could be isolated from those samples heated from 69° C to 73° C after incubation for from 2 days to 3 weeks. This emphasizes the importance of the isolation techniques used for studying heat-stressed organisms. In a study again involving both extra- and intracellularly located *L. monocytogenes* in naturally contaminated milk, Farber et al.[147] reported that though the organism was recovered from milk heated to the 60° C to 66° C temperature range, no viable listeriae were recovered if the isolation was done immediately after treatment at 69° C and above for 16.2 seconds.

The heat resistance of *L. monocytogenes* in dairy products has been reviewed.[117,136,214,320] Mackey and Bratchell[320] summarized the data and found that according to their models, HTST and vat pasteurization of milk would achieve a 5.2 and 39 *D* reduction in the numbers of *L. monocytogenes*, respectively. The *z*-values calculated from heating in sealed tubes and in a slug-flow heat exchanger were 6.1° C and 7.4° C, respectively. These values were close to the overall (all foods and broths) calculated *z* values of 6.7° C to 6.9° C[320] and are close to those values found for *L. monocytogenes* in meats and seafood (Table 44–12).

Two factors known to play a major role in the recovery of thermally treated listeriae led investigators to reappraise the data on the effect of pasteurization on the survival of the organism. The first is called the heat-shock response. If *L. monocytogenes* is exposed to sublethal temperatures of 44° C to 48° C for 20 to 60 minutes before being subjected to the final test temperature, the cells acquire an enhanced thermotolerance. This has been demonstrated both in a milk[156] and in a meat system.[141] In the meat system, heat-shocked cells cooled to 4° C maintained their thermotolerance for at least 24 hours after heat-shock.[141] Cells grown at high temperatures appear to become more heat-resistant. For example, *L. monocytogenes* cells grown at 43° C were more thermotolerant than cells grown at lower temperatures or cells that had been heat-shocked at 43° C for 5, 30, or 60 minutes.[282] In a study of the effect of growth temperature on the thermal resistance of *L. monocytogenes* in HTST pasteurized whole milk following inoculations ranging from 3.0×10^4 to 1.2×10^5 cfu ml^{-1}, the organism survived the pasteurization process in 0 of 4, 2 of 5, and 4 of 4 trials when grown at 30° C, 39° C, and 43° C, respectively.[152] The numbers of *L. monocytogenes* surviving were 0.36 to 0.92 MPN ml^{-1} for cells grown at 39° C, and ranged from 0.03 MPN ml^{-1} to 1.3×10^2 cfu ml^{-1} for cells grown at 43° C. The authors speculated that two different fac-

tors, heat-shock proteins and a highly viscous bacterial membrane, may act individually or interactively at high growth temperatures to confer an enhanced thermotolerance on the cells. In addition to heat, other stress factors such as starvation, ethanol, acid, and H_2O_2 can also lead to enhanced thermotolerance of *L. monocytogenes*.[312] A comparison of $D_{56° C}$ values showed that, compared with control cells (D value = 1.0 minute), the stress of starvation resulted in the highest D value (13.6 minutes). Cells held at lower temperatures (4° C > 10° C > 30° C) maintain their thermotolerance for a longer time than those held at higher temperatures.[262] For example, cells both grown and held at 4° C for 48 hours after a heat-shock of 30 minutes at 46° C were still 2-fold more heat-resistant than nonheat-shocked cells grown at 4° C. Increased thermotolerance of *L. monocytogenes* was observed during slow rates of heating, which was analogous to the induction of the heat-shock response.[478] Maximum thermotolerance was observed at rates of heating of ≤ 0.7° C/minute, while at rates ≥ 5° C/minute enhanced heat tolerance was not observed.

The second factor influencing recovery concerns the methodology used for recovering heat-stressed organisms. Crawford et al.[89] studied the recovery of *L. monocytogenes* cells from inoculated milk heated at 71.7° C in a slug-flow heat exchanger, comparing the effects of enrichment in a nonselective broth (NSB) to the Food and Drug Administration (FDA) and US Department of Agriculture (USDA) enrichment methods. The D values obtained were 2.7 ± 0.8, 1.3 ± 0.4, and 0.7 ± 0.2s for the NSB, FDA, and USDA enrichments, respectively. The use of strict anaerobic techniques can lead to significantly greater recovery of heat-stressed cells than enumeration in the presence of oxygen.[282] For example, $D_{62.8°}$ C values for cells grown at 43° C and recovered anaerobically were at least 6-fold greater than those for cells grown at 37° C and enumerated aerobically. The oxygen sensitivity of heat-stressed *L. monocytogenes* cells was believed to be due to the inactivation of the enzymes catalase and superoxide dismutase during heating.[282] A novel anaerobic method for the recovery of heat-injured *L. monocytogenes* has been developed that uses cysteine and N_2 purging to reduce or eliminate oxidative stresses during enrichment.[281,349] In summary, a reduction in numbers of *L. monocytogenes* in milk of at least 3 logs can be expected after a minimum HTST pasteurization.

In the US, pasteurization standards for frozen dessert mixes require heating for either 30 minutes at 68.3° C or 25 seconds at 79.4° C. $D_{60° C}$ values obtained for nine ice cream mixes ranged from 2.13 to 4.79 minutes, leading to the conclusion that these pasteurization guidelines appear adequate to ensure the inactivation of *L. monocytogenes* in ice cream.[233] The use of common ice cream stabilizers such as guar gum and carrageenan resulted in an increased thermal tolerance of the organism in ice cream mixes.

Information on the heat resistance of *L. monocytogenes* in meats and seafood is shown in Table 44–12. In general, the addition of meat-curing ingredients provides some protection of the organism,[141,531] although this protection may not be evident at temperatures of ≥ 67° C.[532] Chicken gravy was inoculated with *L. monocytogenes* at a level of 10^5 cfu ml^{-1}, and then heated to 50° C, 55° C, 60° C, or 65° C, either immediately after inoculation or after 1, 3, 5, or 10 days of storage at 7° C. $D_{50° C}$ values for strains Scott A and V7 were 119 and 195 minutes at day 0 and 115 and 119 minutes at day 10, respectively. $D_{65° C}$ values were 0.48 and 0.19 minutes at day 0 and 0.016 and 0.007 minutes at day 10, respectively.[236] In contrast, the heating process used commercially for cured and uncured turkey rolls (internal temperatures of 68° C and 74° C, respectively) and battered chicken nuggets (internal temperature of 71° C) was shown to be adequate to reduce 10^7 cfu ml^{-1} of *L. monocytogenes* to below the detection limit.[303] The heating of hot dogs to an internal temperature of 160° F (71° C) resulted in an approximate "3D" reduction in numbers of *L. monocytogenes*.[535] If these products were heated slowly to the final temperature at less than 5° C per minute, the above conclusions would need to be modified to take account of the effect of heat-shock.[14,415,478] Mackey et al.[321] formulated an equation for calculating processing times based on a "7D" inactivation of *L. monocytogenes* in meat, which takes into account the pronounced shoulders on their survivor curves. The equation, $\log_{10}$ processing time = 10.3943 – 0.14618t where t = heating temperature, predicted, for example, that 70° C for 1.45 minutes would be equivalent to a "7D" kill. The authors agreed with Gaze et al.[185] that for the majority of cases, heating at 70° C for 2 minutes would be sufficient to inactivate any *L. monocytogenes* present in raw meat.

In liquid whole egg, the minimal pasteurization schedule recommended by the USDA for this product (60° C; 3.5 minutes) would result in between 2 and 4 log reductions in numbers of *L. monocytogenes*;[24,163,164] however, in a similar product, supplementation with 10% NaCl was protective, resulting in only a 0.2 to 0.6 log reduction after heating.[24] It can be inferred that the incorporation of salt or sugar into egg products will protect bacteria against heat, and the minimum pasteurization schedules for products containing these substances are greater than for those for eggs without these additives. Frying eggs "sunny side up" only slightly decreased (0.4 logs) numbers of *L. monocytogenes*, but scrambling eggs was much more effective, in one instance reducing numbers of the organism by 3 logs.[49]

In a comparison of the heat-resistance in physiological saline of different species of *Listeria* and different serotypes and strains of *L. monocytogenes*, $D_{60°\,C}$ values for *L. monocytogenes* ranged from 0.72 minutes (serovar 1/2a) to 3.1 minutes (serovar 3b).[473] A study of the heat resistance of 27 strains of the organism in tryptone soya broth gave $D_{57°\,C}$ values ranging from 6.5 to 26 minutes.[321] Serotype 1 strains may be more heat-resistant than those of serotype 4.[300] Although far from conclusive, there is some evidence that *L. innocua* may be more heat-resistant than *L. monocytogenes*.[165] For those laboratories not willing or not equipped to work with foodborne pathogens, the latter authors have developed an antibiotic-resistant (chloramphenicol and erythromycin) strain of *L. innocua* for both challenge and heat-resistance studies.

44.7.5 The Effect of Irradiation on Survival

Several studies have examined the irradiation resistance of *L. monocytogenes* in foods and in broth[418] and indicate that for a vegetative cell, the organism is quite radiation-resistant. Of the seven pathogenic bacteria examined, *L. monocytogenes* was the most radiation-resistant in saline solution and chicken breast meat, with D_{10} values of 0.16 to 0.38 kGy.[110] A dose of 3 kGy was necessary for the inactivation of 10^3 cfu g^{-1} of *L. monocytogenes* in air-packed frozen chicken meat.[266] In ground beef, D_{10} values ranged from 0.507 to 0.610 kGy.[361] It was calculated that a dose of 2.5 kGy would inactivate 4.1 logs of *L. monocytogenes* and 5.12 logs of *S. aureus* per gram of ground beef. A treatment dose of 2.6 kGy inactivated 4 logs of the organism in Camembert cheese, with D_{10} values of 0.50 ± 0.05 kGy reported.[47] No statistically significant differences were observed for the radiation resistance of *L. monocytogenes* in various meats; D_{10} values at 5° C of 0.45, 0.47, 0.48, 0.50, and 0.47 kGy were obtained for beef, lamb, pork, turkey breast, and turkey leg, respectively.[491] *Salmonella* were more radiation-resistant than listeriae in these products, with D_{10} values ranging from 0.51 to 0.71 kGy. In a shrimp suspension and with treatment temperatures of –20° C and 0° C, D_{10} values ranging from 0.67 to 0.84 and 0.28 to 0.36 kGy, respectively, were obtained depending on the strain and recovery media used.[51]

Despite the basic differences between electron beam treatment and irradiation by gamma rays from ^{60}Co, their lethal effects on microorganisms are thought to be similar. Electron beam doses of 1.1, 2.2, and 2.9 kGy gave reductions of 2.21, 2.77, and 4.65 logs g^{-1}, respectively, of *L. monocytogenes* in VP (sous-vide) chicken breast.[454] Heat treatment and irradiation were synergistic in their action against *L. monocytogenes*, and this treatment led to an extension of product shelf-life of at least 2 weeks. In a study of electron beam irradiation sensitivity of five strains of *Listeria* spp. inoculated into ground pork, *L. innocua* (D_{10} = 0.638 kGy) was significantly more radiation-resistant than three strains of *L. monocytogenes* (D_{10} = 0.424 to 0.447 kGy) or *Listeria ivanovii* (D_{10} = 0.378 kGy).[487] The authors considered that a total dose of 1.5 to 4.5 kGy, which is currently being considered by the FDA for the irradiation of beef and pork, would be adequate to eliminate *L. monocytogenes* from pork (ie, would be sufficient to give approximately a 3.4 to 10.1 log reduction in numbers).

44.7.6 The Effect of Non-Thermal Treatments on Survival

The desire of consumers for fresher RTE convenience foods that require less chemical preservatives and require minimal processing has led the investigation of processes such as high electric-field pulses, oscillating magnetic-field pulses, intense light pulses, microwaves, and high-pressure treatments. Several studies have examined the sensitivity of *L. monocytogenes* to high hydrostatic pressure treatment[69,292,395,480] and microwaves.[215,225]

44.7.7 Heat-Induced Injury

Many of the selective media currently in use for the isolation of *L. monocytogenes* may not be satisfactory for the recovery of injured cells; investigators have tried to improve the recovery of heat-injured cells by the addition of various compounds. Catalase,[392,393] Oxyrase®,[393] and cysteine[281,349] have been found by some investigators to maximize the recovery of heat-stressed cells in broth, but other workers have not seen any benefit from the addition of catalase.[322,467]

A repair enrichment broth for resuscitating heat-injured *L. monocytogenes* was developed,[65] which contains trypticase soy broth, glucose, yeast extract, magnesium sulfate, ferrous sulfate, sodium pyruvate, and buffers. Heat-injured *L. monocytogenes* repaired themselves in both whole and 2% milk, but the repair process was very sensitive to minor changes in temperature.[356] For example, at 4° C, 10° C, and 26° C, the repair process took 16 to 19 days, 4 days, and 12 hours, respectively. Mackey et al.[322] speculated that although repair may be more rapid at 37° C, it may not recover as many injured cells because they found that the optimal repair temperature was 20° C to 25° C. Obviously, more work is needed in the whole area of heat and/or stress-induced injury.

44.8 PRINCIPLES OF DETECTION AND ISOLATION

Many culture methods for isolation of *L. monocytogenes* from environments such as food have now been developed,[153,314,337] and alternative methods using monoclonal antibodies (Mabs),[91] DNA probes,[98] or PCR[43] are being reported.

44.8.1 Cultural Methods

In the USDA detection procedure for use with meat and poultry,[337] the primary enrichment broth was based on Donnelly and Baigent's[118] *Listeria* enrichment broth (LEB) but was modified to contain nalidixic acid at 20 mg l^{-1}. This was modified further to form the secondary enrichment broth containing acriflavine at 25 mg l^{-1}. The primary broth containing the sample was incubated for 24 hours at 30° C, after which a portion was transferred to secondary enrichment broth. An improved selective medium (LPM agar) was developed containing lithium chloride, phenylethanol, and moxalactam, a broad spectrum antibiotic inhibitory to many Gram-positive and Gram-negative bacteria, as selective agents. The USDA now uses Fraser broth (FB) as the secondary enrichment broth and modified Oxford agar (MOX)[337] as the selective medium. The use of FB facilitates *Listeria* identification as the presence of esculin, and ferric ammonium citrate causes a darkening of the broth in the presence of *Listeria* species. Because many false-negative results have been observed due to reliance on this darkening, the USDA method now calls for all FB cultures to be subcultured to MOX plates after 24 hours of incubation.[10]

Other useful selective agar media include RAPAMY, PALCAM (PAL),[503] and Oxford agar (OXA).[93] Although no one medium has clearly emerged as superior, PAL medium appears to be preferred in Europe, while LPM, OXA, and MOX media are the most widely used in North America. Cultural methods for *Listeria* detection have been reviewed by Curtis and Lee.[92]

The highly selective LPM agar formed the basis of the FDA *Listeria* detection method,[314] which is recommended for the detection of the organism in foods other than meats. Nalidixic acid and acriflavine are used in the FDA enrichment broth (EB), which, in addition, contains cycloheximide, an antifungal agent used to suppress the yeasts and molds often present in foods. Samples are inoculated into EB, and incubated at 30° C for 2 days. At 1 and 2 days, samples are plated onto a selective medium, which was originally modified McBride agar; however, since 1990, LPM and OXA agars have been used.[155] The plates are then incubated for 24 to 48 hours at 30° C and 35° C respectively, for detection and identification.

The Health Protection Branch (HPB), Canada, detection method was developed for all food and environmental samples.[153] Samples are inoculated into LEB and incubated for 48 hours at 30° C. At both 24 and 48 hours, modified Fraser broth (MFB) is inoculated from the LEB culture and incubated 24 hours at 35° C before plating onto OXA agar and one of either LPM, MOX, or PAL for detection and identification.[153]

An HPB enumeration method involves plating the sample on any two of LPM, OXA, MOX, or PAL agars, followed by incubation of the LPM plate at 30° C, and the other selective agar media at 35° C.[145] A presumptive identification and enumeration, based on the colony appearance, are followed by confirmation procedures.

44.8.2 Alternative and/or Rapid Methods

To monitor the incidence of *L. monocytogenes* in foods, methods based on immunological, genetic, or electrical techniques for rapid detection and identification of food isolates need to be designed.[142]

The production of Mabs specific for the genus *Listeria* was first reported in 1987.[139] Recently, the production of a Mab with a high degree of specificity for *L. monocytogenes* 4b was reported.[269] Because this serotype accounts for many of the large foodborne outbreaks of listeriosis, the Mab is of potential interest as the basis of an immunological method.

Methods based on enzyme-linked immunosorbent assay (ELISA) using an antibody (Ab)-antigen (Ag)-Ab sandwich technique are available commercially as Listeria-Tek™ ELISA (Organon Teknika Corp., Durham, NC)[91] and TECRA™ Listeria VIA (Bioenterprises Pty Ltd., Roseville, Australia) kits. In both cases, a sample of the incubated EB is placed in a precoated microwell and incubated for 0.5 to 1 hour, during which *Listeria* cells are captured by the

Ab. Enzyme-conjugated Ab is added at the same time (Listeria-Tek kit) or after a washing step (TECRA kit). After washing, a chromogenic enzyme substrate is added and the color intensity measured with a photometer, yielding a positive/negative result.[289,517] In one comparative study, the results using the TECRA kit agreed completely with the results by a cultural method, while the *Listeria*-Tek kit gave a 23% (7 of 30 samples) false-negative rate.[289] Because the detection limits are 10^4 to 10^5 cfu ml^{-1}, an enrichment step is required for these methods, which increases their overall detection time. An automated ELISA-based system is found in the VIDAS™ Listeria Test (bioMérieux, Marcy-l'Étoile, France), in which the instrument requires no further manipulations after the enriched sample is placed in the reagent strip (Technical Literature, VIDAS Listeria Test, bioMérieux). It uses a genus-specific Ab in a sandwich technique in which alkaline phosphatase is conjugated to the second Ab, catalyzing the breakdown of the fluorescent substrate. The results compared with a cultural method showed 100% sensitivity and 91% specificity (Technical Literature, VIDAS Listeria Test, bioMérieux).

An interesting adaptation of the ELISA detection method has been developed in the coating of magnetic beads with an anti-*Listeria* Ab, as in the DYNABEADS™ (Dynal Inc., Great Neck, NY) and Listertest™ (Vicam, Somerville, MA) kits. The Ab-coated magnetic beads are added to the sample and incubated with gentle mixing for 1 to 2 hours (Technical Literature, DYNABEADS, Dynal; Listertest, Vicam). The beads, with their bound *Listeria* cells, are placed in a magnetic field for separation from the sample and washing. Once separated, cultural or rapid detection methods can be applied, thus eliminating the need for an enrichment step.[250]

The detection of *L. monocytogenes* by colony hybridization with a radioactive-labeled DNA probe, which is based on the *hlyA* gene and is specific for *L. monocytogenes*, was first reported by Datta et al.[97] From sequencing information obtained from this probe, a 20-mer oligonucleotide probe was developed and used as a synthetic probe in a colony hybridization method to identify β-hemolytic *L. monocytogenes* in ground beef, with 100% specificity.[360] To avoid the problems associated with the use of radioactivity, the natural probe has since been chromogen-labeled with horseradish peroxidase and used in the enumeration of the organism in foods with 100% sensitivity.[98] The probe also has been labeled with alkaline phosphatase and used for direct colony hybridization on hydrophobic grid-membrane filters (HGMF).[530] In a comparison with the HPB standard method,[153] the HGMF DNA probe method was highly specific in discriminating *L. monocytogenes* from other *Listeria* species present in the food samples. The use of anti-DNA-RNA Mabs specific for hybrid nucleic acid (HNA) molecules formed a new approach to the detection step in a DNA probe method for *Listeria* species.[162] Using a double-sandwich ELISA to detect HNA formation, the authors were able to detect as little as 2.5 pg of target RNA, or 5×10^2 cfu ml^{-1} of *Listeria* species in foods.

Commercial hybridization assay kits are now available, based on DNA probes targeted to genus-specific regions of 16S rRNA (Gene-Trak Systems, Framingham MA) or *L. monocytogenes*-specific rRNA (Gen-Probe, San Diego, CA). The Gene-Trak™ probe solution, added after enrichment of the food sample, contains two probes that hybridize to adjacent regions of the target *Listeria* rRNA. The polyadenylate tail on the capture probe hybridizes to plastic dipsticks coated with complementary polydeoxythymidine. The detector probe also contains a ligand, fluorescein. When the dipstick is transferred to an enzyme-labeled antifluorescein Ab, the presence of the target-probe complex is visualized by means of a substrate.[90] When the performance of the Gene-Trak method was compared with the USDA or FDA cultural methods and used on the appropriate food, the agreement between methods was 82%.[90] Gene-Trak has since developed an *L. monocytogenes*-specific probe to use as the capture probe (Technical Literature, Gene-Trak).

Using PCR for the detection of *L. monocytogenes* in food and concentration of enrichment broths by centrifugation, the lower limit of detection in most foods was about 10 bacteria $(10g)^{-1}$; all the naturally contaminated foods in which *L. monocytogenes* was detected by cultural testing were also positive by the PCR test.[372] The total analysis time for the PCR test was 32 hours. A method for direct extraction of DNA from foods and testing by PCR was described that enabled the detection of 10^3 to 10^4 cfu *L. monocytogenes* g^{-1} of food.[103] The primers that have been used for the detection of *L. monocytogenes* are shown in Table 44–13. *L. monocytogenes* was among the pathogenic organisms detected in foods after the direct application of PCR to extracted DNA, the bacterial cells being detected at 10^3 to 10^4 cfu ml^{-1}.[103] An alternative to analysis by gel electrophoresis is to use an RNA probe that hybridizes specifically to the desired PCR product and is detected by an anti-RNA-DNA hybrid Ab.[42] A specific oligonucleotide coupled to paramagnetic beads has been used to isolate listerial DNA from foods.[374] The isolated DNA was amplified by PCR, with a detection

Table 44–13 Genes Targeted in PCR for Detection of *Listeria monocytogenes*

Gene	Food/Pure Culture	Sensitivity (cfu g^{-1})

Source: Data from A.R. Datta and M.A. Benjamin, Advances in Nucleic Acid-based Techniques for Detection of Listeria Monocytogenes, *Proceeding of the 12th International Symposium on Problems of Listeriosis*, October 2–6, 1995, Perth, Australia.

limit of 1 to 10 cfu 10 g^{-1} of food.[25] PCR can be affected by the presence of inhibitors in samples and the technique detects both live and dead cells. It seems that, at the present time, PCR is preferably used as a screening technique.

In a comparison between Gen-Probe DNA probe and a PCR technique, although both techniques showed high specificities, the sensitivity of the Gen-Probe method was low.[373] The report concluded that PCR applied after a two-step enrichment process was the most sensitive method for detecting *L. monocytogenes* in soft cheeses.

Electrical detection methods measure changes in conductance or impedance of the medium during microbial growth.[221] These methods detect *Listeria* species in hours rather than days. Media specific for the growth of this pathogen are required for the successful application of this method.[68]

44.8.3 Identification Methods

Miniaturized multitest assays are commercially available for the identification or confirmation of presumptive *Listeria* isolates to the species level. The API-Listeria™ test (API-bioMérieux Inc., Marcy-l'Étoile, France) uses 10 biochemical tests for identifying *Listeria* isolates to the species level, following a 24-hour incubation. When combined with the detection of β-hemolytic activity on blood agar plates, all of the 70 *Listeria* strains tested were correctly identified.[177] Tests of 65 strains of *Listeria* species showed that the API-ZYM system (API-bioMérieux), which uses detection of 19 constitutive enzymes, could be used for the rapid (4 hour) confirmation of *L. monocytogenes*.[100] In the Mast ID™ system (Mast Laboratories, Bootle, UK), carbohydrate substrates and a pH indicator are incorporated into agar plates, which can be used to screen up to 21 isolates per plate to identify *Listeria* species.[273] The MICRO-ID™ LISTERIA system (Organon-Teknika) uses 15 biochemical tests to identify *Listeria* to the species level after 24 hours incubation. In the case of 99% (409 of 414) of the strains, the cAMP test was also needed for correct identification of strains.[20] A collaborative study involving 13 laboratories, each testing 97 food and environmental isolates, evaluated the AutoMicrobic System (bioMérieux Vitek Inc). This kit, which uses up to 30 biochemical tests, is scanned hourly in the system for turbidity and/or color changes and correctly identified 91% of *Listeria* species and 100% of non-*Listeria* species.[217]

A colony-confirmation test, based on a DNA probe, forms the basis of the commercially available Accuprobe™ *L. monocytogenes* Culture Identification Reagent Kit (Gen-Probe). Using an acridinium ester-labeled DNA probe, this chemiluminescent method was reported to be 100% sensitive and 100% specific when tested on a total of 70 *Listeria* strains[375] for the rapid confirmation of 296 suspect *L. monocytogenes* colonies.[387]

PCR used in the identification of presumptive *L. monocytogenes* isolates during routine analysis by the HPB method showed 100% sensitivity and 100% specificity.[43]

44.8.4 Tests for Virulence

Since *L. monocytogenes* was first isolated, workers in the field have stated the need for simple, rapid procedures to differentiate isolates of this species from nonpathogenic *Listeria* spp., without resorting to animal inoculation. Several procedures that demonstrate hemolysin production were proposed to meet this need. The simplest test for the presence of β-hemolysis is the appearance of zones of clearing on horseblood agar plates. However, these are often difficult to interpret with *L. monocytogenes* and *L. seeligeri* because strains vary in the intensity of their reaction. Recently, hemolytic ceftazidime lithium chloride agar (HCLA) was developed as a differential medium for *L. monocytogenes*.[410] When horseblood agar is incorporated into the agar overlay, which is poured over the selective medium containing lithium chloride, colistin methane sulfonate, and ceftazidime, *L. monocytogenes* forms blue-gray colonies surrounded by zones of β-hemolysis. The cAMP phenomenon, originally noted with Group B streptococci, was adapted for use with *Listeria* species by the addition of a streak of *Rhodococcus equi*, which enabled *L. ivanovii* to be differentiated from *L. monocytogenes* and *L. seeligeri* by their opposite reactions with the hemolysins of the two test organisms.[142]

The chick embryo test, where the chorioallantoic membrane of 10-day-old chick embryos is inoculated with *Listeria* strains, is an alternative assay to the mouse pathogenicity test.[489] When a comparison of the two methods was made using 20 *Listeria* strains, a good correlation was found.[381]

Continuous cell lines have also been proposed as a test for pathogenic *Listeria* species. Chinese hamster ovary cells were the most sensitive among eight cell lines, when culture filtrates from *L. monocytogenes*, *L. ivanovii*, *L. innocua*, *L. murrayi*, and *L. grayi* were tested for a cytotoxic effect.[140] A 6-hour virulence assay was developed using hybridoma and myeloma cells from murine and human sources and evaluated for its usefulness in *in vitro* virulence testing.[38] Three hybridoma cell lines and a murine myeloma line were equally sensitive to virulent *Listeria* species.

44.9 CONTROL

Methods used to control *L. monocytogenes* involve the implementation of basic quality assurance systems such as hazard analysis critical control point (HACCP) procedures from "farm to fork." Many of the problems in food plants linked to final product contamination with *L. monocytogenes* have been due to postprocessing contamination (Figure 44–1). Once the organism contaminates a food processing plant, it can survive there for a long time, especially if the temperature is low and the organism is protected by food components.[390] When suspended in saline or milk, *L. monocytogenes* can survive on fingertips for up to 1 hour and 5 hours, respectively; hand washing with soap usually fails to decontaminate the fingertips.[470] Postpasteurization contamination of food products with listeriae can occur in processing plants via aerosol formation,[201] and the organism can survive for longer than 3 h when present in large numbers in aerosol suspensions.[476] Environmental and in-line sampling have located problem areas and revealed plant conditions that may contribute to final product contamination. With this knowledge in hand, much effort has been expended by the dairy, meat, and fish industries to improve sanitation, hygiene, and general cleanliness inside food processing operations.

44.9.1 Control in the Dairy Industry

General Aspects

Raw milk is contaminated with *L. monocytogenes* either by secretion of the organism directly into the milk by a mastitic cow[197], or an asymptomatic carrier,[150] or by environmental contamination of the udder via soil and/or animal waste in the barn area. A study of more than 8,800 environmental samples from 62 dairy plants revealed that *Listeria* were isolated most frequently from floor drains (38%) and conveyor belts (36%).[369], This is consistent with findings that the organism can be isolated frequently from wet sites within plants, and that fluid milk and plants producing frozen products were more frequently contaminated with the organism than either butter, processed cheese, natural cheese, or dry product plants.[369] The high level of condensate in fluid milk and frozen products plants may play a role in postprocessing contamination. To understand some of the difficulties industry faces in trying to operate in a *Listeria*-free environment, some of the other sites in addition to drains and conveyor belts found to be contaminated with *Listeria* in the 62 dairy plants include: clean-in-place (CIP) rinse tank, case washer water, glycol solution, butter remelt area, return dumping area, hog feed tank drain, roof evaporator drip pan, driveway pit, main entrance, office, and shop.[369] In addition, *Listeria* are frequent contaminants of raw materials used in the plants, and therefore, the organism is continually reintroduced into the plant environment.

Several controls for *Listeria* can be applied at the farm level. A case-control study of 128 selected dairy farms in France revealed that poor silage quality, inadequate frequency of cleaning the exercise area, poor cow cleanliness, insufficient lighting of milking barns and parlors, and incorrect disinfection of towels between milkings were significantly associated with milk contamination by *L. monocytogenes*.[441] The following control measures should be considered.

Next Page

- Any cow with slightly hardened quarters should be treated promptly with antibiotics, and areas in the vicinity of aborted cows should be disinfected.
- Mastitic cows should be separated from the rest of the herd.
- Drinking water for cattle should be of good microbiological quality.
- Fields should not be irrigated with effluents from sewage treatment plants or fertilized with untreated sludge from sewage treatment plants.
- Sound milk-collection techniques should be practiced, including teat-dipping and drying and sanitization of all milk contact surfaces just before use.
- The temperature of the bulk-tank should be monitored and kept as low as possible.[82,106,481]

Control at the Dairy Plant

Detailed information is given in several reviews.[82,106,362,366,481] There are four major ways of introducing *L. monocytogenes* into the dairy plant: via contaminated milk, via contaminated materials and equipment, via the environment such as from the air or by pests, or via plant workers, truck drivers, or visitors carrying the organism into the plant. Milk trucks should be properly disinfected, and milk truck drivers should not walk through the production facilities of a plant. Because *L. monocytogenes* can multiply in naturally contaminated raw milk,[150] the temperature in milk silos should be monitored and kept as cold as possible. The following measures can be used to control the organism.

Isolating Processing Areas from Raw Product Areas. Generally, unauthorized personnel should not be allowed into the plant. Traffic patterns must eliminate the potential for cross-contamination (eg, as far as possible, personnel within the plant should not walk from the raw product area to the processing area; for those employees who must do so, footbaths should be installed and managed properly). All outer garments worn in the plant, including boots, should be sanitized daily. Color-coded outer garments should be used to identify the area of the plant to which personnel are assigned. The airflow within a plant should move from finished product area to the outside or to the raw material receiving area. Raw materials should never be stored with finished product. Only those products that have not left the direct control of the dairy should be reworked. Refrigerated nonsterile products should not be returned to the factory when their shelf-life has expired. Reworked products should be set aside in a separate area until they are reprocessed. A general principle is to treat reworked products as raw product. Employee education programs are crucial to success, and must be backed up by the appropriate management action. This would include education of employees on the basics of Good Manufacturing Practice (GMP), provision of the latest technology in terms of sanitation practices, provision of trained supervision, elimination of contamination sources from clean employee environments, and provision of constant feedback and encouragement.

Processing Controls. The proper use and maintenance of pasteurizers is of primary importance. Accurate records on pasteurizer performance must be kept and inspected daily. Sweetwater should be treated with biocide. Air entering a plant should preferably be filtered (gross filters) and the air intake located away from any outside area that may harbor *Listeria*, such as the raw milk receiving or refuse-containing areas. Makeup air should not be taken from dirty areas. Air incorporated into dairy products, such as ice cream, should be filtered through bacterial or high efficiency particulate air (HEPA) filters. Aseptic packaging and processing areas should also be supplied with HEPA-filtered air. All walls, ceilings, and floors must be smooth with no cracks, as *L. monocytogenes* can accumulate in these areas. The processing area should be kept as dry as possible, since *L. monocytogenes* is frequently found in wet areas of the plant.[279] Condensation in processing and packaging areas may be reduced by dehumidifiers and/or air conditioners. Cross-connections between finished and raw product (including CIP lines) should be eliminated. All processing environments should also be kept as cold as possible.

Cleaning and sanitizing. All areas of the plant must be thoroughly cleaned on a regular basis. This should include drains, air handling systems, conveyor belts, cold storage areas, walls, ceilings, floors (including sanitizing floor mats and foot baths), drains, pallets, conveyor belts (tracks), milk cases, case washers, and cold storage areas.[77,279,518] However, priority should be given to product contact surfaces. Of 39 frozen milk plants in California, those plants with above-average sanitation had a much lower rate of recovery of *Listeria* than plants with below average sanitation.[518] In general, sanitation systems must be proven effective with appropriate verification. Cleaning and sanitizing must be given a high priority, as should personnel chosen to oversee the effectiveness of the program. Any spilled dairy products should be wiped up and the immediate area cleaned and sanitized. Items that absorb water, such as rags and sponges, are potential sources of *L. monocytogenes* contamination and should not be reused for cleaning without being sanitized. The use of color-coded brushes for different areas of the plant should be considered. Effective sanitation guidelines for dairy plants have been published.[82,366] Consultation and guidance from the chemical manufacturer are highly recommended. Each processing plant usually has different requirements for cleaning agents, and therefore compound formulations may be designed for each type of cleaning operation. No single hygiene program will fit all the different types of production and processing facilities. In general, on food contact surfaces, listeriae can be inactivated by using sanitizers based on sodium hypochlorite, iodine complexes, quaternary ammonium compounds (QUATs), and anionic acid sanitizers. For nonfood contact surfaces, a combination of thorough cleaning (high pressure, foam, or manual operations) with chlorinated alkaline cleaners, followed by a potable water rinse and a surface sanitizer usually is recommended.[111] Sanitizers are generally more effective against *L. monocytogenes* that are attached to nonporous rather than porous surfaces.[324] It is generally recognized that to properly control listeriae, sanitation programs must go well beyond those previously thought to be adequate.

Environmental and Product Sampling. Environmental sampling should be done to test the efficacy of the sanitation program and also to pinpoint possible "hot spots" in the plant where *L. monocytogenes* may colonize.[178,522] Drains are good indicator sites of the environmental status of the plant.[77] Guidelines both for taking and analyzing environmental swabs and in-line samples for the presence of *L. monocytogenes* in meat plants have been published.[178] Testing for *L. monocytogenes* in the finished product as the sole means of control is not an efficient way of ensuring a safe product. The HACCP system now being implemented by industry uses finished product testing only as a means of verifying that GMPs are in place.

44.9.2 Control in the Meat Industry

Many of the control points outlined in the section on the dairy industry also apply to the meat and seafood industries. Both the Canadian government and the American Meat Institute have published information handbooks on the control of *L. monocytogenes* in RTE meat products.[8,178] Some of the places where *L. monocytogenes* has been found in meat plants, listed approximately in the order of prevalence, are floors, drains, sponges and brushes, food contact surfaces, condensate, walls and ceilings, and compressed air.[28] Other potential problem sites include conveyor belts, transport containers, cutting tables, equipment and boards, air above fans, air conditioners, humidifiers, employees' clothing and hands,[186,187] exhaust hoods, gutters, and pickling systems.[8,186,522] Control can require expensive modifications of existing plant infrastructure or equipment.

Because it is nearly impossible to eliminate *L. monocytogenes* from raw meat, most control procedures aim at minimizing levels in raw meat, avoiding cross-contamination of processed product, preventing multiplication of the organism in products, and preventing its establishment and growth in the environment of the meat plant.[497] There is also a need for increased attention and education for retail operators, especially those with delicatessen counters.[3] *L. monocytogenes* was isolated from the hands of 3 of 10 delicatessen workers from four different establishments.[275] Cross-contamination of foods has occurred in retail outlets.[3,252] For example, if soft-cheese wheels are cut at the retail level by a single knife, contamination of one wheel could result in cross-contamination of many other cheeses that are cut by the same knife. On the cheese surface, the organism could multiply to high numbers during storage on the retail shelves and in the consumer's refrigerator.[17,188] This can also occur with meats cut by a retail meat slicer.[243] Measures aimed at control include:[8,178,497,498]

- improvement of slaughterhouse hygiene
- separation of raw meat and thermally processed meat areas
- regular, proper, and effective cleaning and sanitation programs
- disinfection of hands, especially in the processing and postprocessing areas, with regular changing of gloves[186,187]
- pressure hoses not being used to clean drains, since resulting aerosols can spread contamination throughout the room
- identifying and establishing procedures to deal with possible high-risk circumstances (eg, introduction of new product onto line)
- no direct access from outside the plant to the production and packaging areas for personnel or equipment such as forklifts

- effective processing schedules with immediate cooling
- recontamination of cooked meat products should be avoided and the use of cook-in-the-bag processing or immediate aseptic packaging of finished product encouraged[261]
- maintenance of a dry environment within the meat plant
- commitment of management to provide education and training to plant personnel
- establishment of an effective environmental sampling program to verify the effectiveness of the control programs, with routine sampling of environmental surfaces
- the use of "clean rooms" for meat plants designed to prevent recontamination of heated meat products should be considered and a "clean room mentality" established within the RTE product area.[28,299]

Unless properly applied, cleaning and disinfection procedures will not minimize the levels of this organism, leading to loss of control.[440,498] Floors are particularly difficult areas to maintain free of *Listeria*, especially during the summertime. Equipment should be designed and constructed so that it is easily cleaned, and without corners. It may take from 6 months to 2 years to bring a plant under control.[498]

Environmental sampling of a turkey frankfurter plant, whose product had been linked to a case of listeriosis, showed that contamination of the majority of frankfurters occurred at a single point during the peeling process, just before packaging.[522] A properly applied HACCP-based sampling plan may have pinpointed this process in the plant, and thus eliminated contamination of the final product. In addition to the use of HACCP, research is continuing on the use of additional hurdles or barriers to control the growth of *L. monocytogenes* in meat and poultry products. This would include the addition of chemical compounds and/or the use of starter cultures such as the lactic acid bacteria and their bacteriocins.

44.9.3 Compounds Used To Inhibit or Inactivate *L. monocytogenes*

Compounds that are used most commonly by the food industry and that are effective against *L. monocytogenes* include iodophors such as iodine (25 ppm); acid sanitizers (130 to 200 ppm); chlorine at a wide range of concentrations (20 ppm free available chlorine for water treatment; 200 ppm for CIP cleaning, walls, stainless steel equipment, and nonporous surfaces; and 1,000 ppm for wooden crates and fogging of the atmosphere) and QUATs at 200 ppm.[85,129,310,368,500] A new buffered organic acid anionic surfactant was also effective (> 5 log kill after 30 seconds) against *L. monocytogenes* at a concentration of 0.6%.[423]

The presence of organic material and the attachment of microorganisms to surfaces can reduce the efficacy of disinfectants against *L. monocytogenes*.[32,368] Bacteria within a biofilm are generally more resistant to physical and chemical antimicrobial factors than are freely suspended bacteria.[168,296] On surfaces that are irregular or difficult to reach, survivors might form biofilms, resulting in increased resistance to sanitizers and heat and they could then contaminate foods.

44.9.4 Use of the Hazard Analysis Critical Control Point System

HACCP procedures should be applied during production of foods, at the retail level, and in the home. Because *L. monocytogenes* can grow at chill temperatures, a product that may have contained very low numbers immediately after leaving the processing plant could contain large numbers by the time the food is consumed. This is especially true in the case of the new generation refrigerated-type foods with extended shelf-life. For these foods, it is necessary to add additional barriers or hurdles to control the growth of *L. monocytogenes*. Controls at both the retail and consumer levels include prevention of cross-contamination and maintenance of chill cabinets and refrigerators at as low a temperature as possible.

44.9.5 Regulatory Policies

Unfortunately, control measures for *L. monocytogenes* in foods are also influenced by differing worldwide government policies regarding the presence of the organism in food—a problem compounded by the lack of knowledge regarding the numbers of cells that must be ingested to cause illness.[230,231] Whether or not food regulatory agencies worldwide should tolerate low levels of *L. monocytogenes* in foods in which the organism cannot grow is still debatable at this point. However, every effort should be made to inhibit multiplication of the organism in foods. It has been suggested that all strains of *L. monocytogenes* should be regarded as potentially pathogenic.[342] Despite the unknowns, the HACCP approach is the most reasonable path to follow to reduce and/or eliminate *L. monocytogenes* in foods. The *L. monocytogenes* policies of various countries are outlined briefly below.

North America

Following the large listeriosis outbreak in 1985 that was clearly linked to the consumption of Jalisco cheese,[306] a "zero tolerance" policy was instituted that required an absence of *L. monocytogenes* in 50g of food. Despite subsequent debate, this policy has not been altered;[323,347] however, the number of listeriosis cases and deaths in the US for the years 1989 to 1993 decreased by 44% and 48%, respectively.[486] The decreased rates were seen in both the perinatal and nonperinatal populations. An outbreak of listeriosis in the US between August 1998 and February 1999, which has affected at least 70 people and caused 20 deaths, is thought to be associated with the consumption of hot dogs and deli meats.[74a] This outbreak, which occurred after it was thought that industry had brought the problem under control, has caused renewed concern about *L. monocytogenes* in the US.

Canada, meanwhile, had the opportunity to develop a compliance guide in the absence of a crisis situation, which led to a flexible policy.[146] The Canadian regulatory policy on *Listeria*-contaminated foods, based on the principles of HACCP, was developed using a health risk-assessment approach.[146] The policy reflects current knowledge that the risk of contamination by *L. monocytogenes* can be reduced, but the organism cannot always be eradicated from finished product or the environment. The policy directs inspection and compliance action to RTE foods that are capable of supporting growth of the organism. The highest priority is given to those RTE foods that have been linked causally to listeriosis and those with a shelf-life greater than 10 days. The policy is based on a combination of inspection, environmental sampling, and product testing. Foods have been placed into three categories based on health risk. Products in Category 1 have been linked causally to outbreaks of listeriosis and receive the highest priority in inspection and compliance activities. The presence of *L. monocytogenes* in these RTE foods will trigger a Class I recall with consideration of a public alert. Category 2 contains all other RTE foods that are capable of supporting growth of *L. monocytogenes* and have a shelf-life exceeding 10 days. The presence of *L. monocytogenes* in these products requires a Class II recall with possible consideration of a public alert. Category 3 contains two types of RTE food products: those supporting growth with a ≤ 10-day shelf-life and those not supporting growth. For Category 3 RTE foods, factors such as the presence or absence of GMP, levels of *L. monocytogenes* in the food (action level 100 cfu g^{-1}), and/or a health hazard evaluation are all considered in the compliance action taken.

Europe

The UK government only has specific legislation for *L. monocytogenes* in cheese and other milk-based products[11] and is now required to put into the UK food regulations, microbiological standards included in Directives issued by the European Community (EC). The EC directive on milk and milk-based products, which is the same as the UK legislation, states that *L. monocytogenes* should not be present in 25g ($n = 5$, $c = 0$) of soft cheese and should be absent in 1g of other products.[341] In addition, the Public Health Laboratory Services (PHLS) has established provisional guidelines for some cooked RTE foods at point of sale.[191] The four categories developed along with their action levels include: (1) satisfactory (*L. monocytogenes* not detected in 25g), (2) fairly satisfactory (present in 25g at levels of <100 cfu g^{-1}), (3) unsatisfactory (100 to 1000 cfu g^{-1}), and (4) unacceptable/potentially hazardous (> 1000 cfu g^{-1}).

Germany has developed recommendations to be used by food inspection authorities.[490] Four different categories of food have been developed along with action levels. Group I consists of foods for infants and small children as well as dietary foods, with the action level being the presence of *L. monocytogenes* in 25g of product. Group II contains foods such as pasteurized milk and aseptically packaged products, with the same action level as Group I foods. Foods in Group III include frozen meals, cheese (but not raw-milk cheese), prepacked sausages and shrimp, with an action level of >100 cfu g^{-1}. Low-level contamination would precipitate follow-up action in the plant, and higher contamination would render a food "unfit for human consumption." The last group (Group IV) consists of three different food categories that are "otherwise stabilized foods," such as smoked fish and fermented sausages; raw foods consumed in the raw or unprocessed state; and raw food that is heated before consumption. For Group IV foods, *L. monocytogenes* levels of < 100 cfu g^{-1} usually are permissible, but in cases where higher levels are observed, the food plant or shop would be inspected. The upper limit of *L. monocytogenes* allowable in any food product is currently 10^4 cfu g^{-1} or ml^{-1} (action level, not tolerance value), but authorities are considering lowering this to 10^3 cfu g^{-1} or ml^{-1}.[490]

Australia

Standards limiting *L. monocytogenes* contamination of foods are not yet incorporated into the Australian Food Standards Code. State government agencies will intervene to prevent the sale of foods contaminated with the organism;[132] however, different policies and attitudes prevail in the various state agencies, creating some confusion. Export control orders are more stringent than the Foods Standards Code and already require the absence of *L. monocytogenes* from 5 × 25g samples of many cheeses. The National Food Authority is considering the introduction of standards for the organism into the Food Standards Code. Although the Authority previously rejected a zero-tolerance approach for the organism in liquid and powdered milk as well as cream, it is currently considering adopting a zero-tolerance policy (absence in 5 × 25g) for foods associated with *Listeria* outbreaks and foods capable of supporting growth of the organism.[132] As in the Canadian approach, products will be grouped on the basis of ability to support the growth of *L. monocytogenes*, and information from predictive models will be used.

The International Commission on Microbiological Specifications for Foods (ICMSF) has developed a policy mainly for the international trade of foods containing *L. monocytogenes.*[246] Cases and sampling plans for the organism were based on principles published previously.[245] A decision tree (divided into four steps) for the choice of cause for *L. monocytogenes* is presented. Step I asks if the food is intended for highly susceptible individuals; step II if the food has been epidemiologically linked with listeriosis; step III if the food has a history of high levels of the organism, and questions its potential for supporting growth of the organism; and step IV if the food will receive a listericidal treatment before consumption. For food intended for normal individuals, the ICMSF recommends, n (ie, number of samples) values of 5, 10, or 20 with a small m of ≤ 100 cfu g^{-1}, and for food intended for highly susceptible individuals n values of 15, 30, or 60 with a small m of zero in 25g. The requirement of ≤ 100 cfu g^{-1} of food applies at the point of consumption.[247]

In addition to these policies, each country listed above has published educational brochures and pamphlets targeting the high-risk populations. For example, in Australia, billboards have been placed on the back of city buses warning pregnant women about the risk of foodborne listeriosis. Dietary guidelines have also been published by the respective government agencies; these include advice on safe food handling, and advice to high-risk groups to avoid the consumption of soft cheese and pâté.

44.10 CONCLUDING REMARKS

Although listeriosis has been described for many years, the demonstration of foodborne transmission of the organism has made it a major concern to the food industry. *L. monocytogenes* can contaminate nearly all kinds of food and can grow on many foods even at refrigerator temperatures. Methods for isolating *Listeria* have been developed, although comparative studies have shown that no one procedure gives consistent isolation from all contaminated samples. Optimization of rapid detection methods for this bacterium in foods is now required.

The virulence factors of *L. monocytogenes* have been identified genetically, allowing the design of rapid methods to detect the organism in foods. Molecular typing of wild strains demonstrates the heterogeneity of virulence within the species, and the study of epidemic strains shows a low number of closely related clones. Perhaps the epidemic strains share one or a few specific properties that could explain their causing large outbreaks.

Surveillance systems should be initiated so that time-space clusters can be detected, and common source outbreaks identified, investigated, and prevented. They could also help to explore the differences in reported incidences, which may be due to environmental factors, host susceptibility, or dietary exposures. Infections caused by contaminated foods need to be more precisely defined by epidemiological investigations, including strain typing.

45.1 INTRODUCTION

From the early recognition of *Salmonella* spp. as the etiological agent for human typhoid fever and cholera in swine,[88,403,578] public health and socioeconomic concerns on the occurrence of these bacteria in the global food supply progressively led to the identification of *Salmonella* reservoirs, to the characterization of epizootic and zoonotic cycles of infection, and to the human health impact arising from the massive production and marketing of foods for national and international markets. Historically, the international trade of agricultural and food products contributed to the introduction and spread of new *Salmonella* strains in importing countries. For example, the emergence of *Salmonella* Agona in the United States (US) and the United Kingdom (UK) nearly three decades ago stemmed from the importation of contaminated Peruvian fish meal.[409,451,608] The microorganism, which rapidly spread within the meat animal industry and in human populations, continues to figure in the national epidemiological registries of these countries.[69] Imported animal feeds were also incriminated as the source of *S.* Hadar in turkey flocks, and of *S.* Indiana and *S.* Saint-paul in the poultry industry of the UK between 1959 and 1961.[409] During World War II, contaminated dried eggs imported into the UK from North and South America were diverted principally to the swine industry as feedstuff. This practice reportedly introduced *S.* Panama into the human food chain of the importing country and led to numerous episodes of human salmonellosis.[409] The widespread occurrence of salmonellae in internationally distributed animal feeds and feed ingredients has been, and undoubtedly continues to be, responsible for the emergence of novel *Salmonella* serovars in meat products and in human foodborne disease.

Recent decades have also witnessed the emergence of new foods as sources of human *Salmonella* infections. Chocolate, which was generally considered to be a safe food product, was implicated in a major Canada-US outbreak of *S.* Eastbourne in 1973. Cocoa beans presumably imported from Africa were tentatively identified as the source of contamination.[177] Several episodes of human salmonellosis from the consumption of internationally distributed chocolate products were reported in subsequent years.[164] In the past, limited survey data suggested a low prevalence of *Salmonella* spp. in fresh fruits and vegetables, and occasional episodes of human salmonellosis were attributed to these products.[164] Although melons, notably watermelons and cantaloupes, were primarily responsible for the isolated fruitborne outbreaks from 1950 to 1991, the consumption of other products such as tomatoes and orange juice has resulted in cases of human salmonellosis. Similarly, the historical prominence of spices as a potential source of human salmonellosis is currently being overshadowed by the growing importance and disease potential of other vegetables, notably leguminous sprouts.[166]

Poultry, pork, and beef products, in decreasing order of importance, continue to figure prominently as the principal reservoirs of human foodborne salmonellosis. Efforts to control the spread of salmonellae in the rearing and slaughtering sectors have met with limited success due, in part, to the uncoordinated implementation of control measures in these vertically integrated industries.

Although S. Typhimurium has consistently headed national listings of serovars implicated in human disease before 1985, its dominance was challenged by S. Enteritidis, which now prevails in many countries as the most important disease-associated serovar.[160,705] The association of S. Enteritidis with poultry products, notably shell eggs, contributed significantly to this phenomenon of serovar succession.[4,11,447] Early reports on the pathogenicity of *Salmonella* indicated that ingestion of high numbers (10^5 to 10^7) of foodborne salmonellae was a prerequisite for human illness.[164] However, more recent evidence suggests that a single *Salmonella* cell may constitute a human infectious dose.[166] Major efforts to educate consumers and workers in food service establishments continue to yield disappointing results as evidenced by the persistence of improper handling and inadequate cooking of foods as the principal causes of bacterial foodborne outbreaks.[653]

This chapter assesses the magnitude of the *Salmonella* problem in the global food chain based on epidemiological, pathogenic, and ecological considerations and underlines the role of control measures at all levels of food production, manufacture, and distribution and of reliable analytical methods as prerequisites to the safety of the food supply.

45.2 TAXONOMY AND CHARACTERISTICS OF THE ORGANISM

Salmonella spp. are facultatively anaerobic Gram-negative (GN) rods within the family *Enterobacteriaceae*. Members of this genus are motile by peritrichous flagellation except S. Pullorum and S. Gallinarum, which lack flagella.[39] Nonmotile variants can also arise as a result of a faulty assembly of flagellar subunits or deficiencies in the motor functions of these appendages.[432] Salmonellae grow optimally at 35° C to 37° C, catabolize a variety of carbohydrates into acids and gas, use citrate as the sole carbon source, produce H_2S, and decarboxylate lysine and ornithine to cadaverine and putrescine, respectively. These microorganisms are oxidase-negative and catalase-positive with a 50 to 53 mole % guanine plus cytosine (G + C) DNA content.[404] Historically, an isolate from selective plating media was most likely to be confirmed as *Salmonella* if it catabolized glucose and lysine but failed to metabolize lactose, sucrose, and urea. The reliability of these diagnostic traits is being undermined by the widespread exchange of genetic elements between compatible bacterial strains in the environment.[278,364] Atypical *Salmonella* biotypes that cannot decarboxylate lysine[325,400,472] or that readily use lactose,[278,364,429,571,646,661] sucrose,[364,520,549] and urea[232,374] have been isolated.

Several schemes based on biochemical characteristics, DNA homology, and enzyme electrophoretic patterns have been used for the taxonomic classification of salmonellae. In 1966, Kauffmann used determinant biochemical traits to separate the *Salmonella* group into four subgenera (I to IV) with each serovar given species status.[381] A fifth subgenus (V) was subsequently recognized.[404] The main characteristics of each subgenus included the ability to use dulcitol (subgenus I), dulcitol and malonate (subgenus II), malonate and o-nitrophenyl-β-D-galactopyranoside (ONPG) (subgenus III), growth in KCN (subgenus IV), and failure to metabolize dulcitol and malonate and ability to catabolize ONPG and grow in KCN (subgenus V). In 1972, Ewing proposed another taxonomic scheme that recognized only three species within the *Salmonella* group. These included S. Typhi (single serovar), S. Choleraesuis (single serovar), and S. Enteritidis, which encompassed all of the remaining serovars. Members of the *Arizona* group were assigned to a distinct *Arizona* genus.[229] This scheme was structured on the differential utilization of 15 substrates and production of hydrogen sulfide gas. A third taxonomic scheme based on phenetic and DNA homology characteristics recognized S. Choleraesuis as the sole species subdivided into seven subspecies including subspecies *choleraesuis*, *salamae*, *arizonae*, *diarizonae*, *houtenae*, *bongori*, and *indica*.[407] In 1987, the latter scheme was modified to recognize *S. enterica* as the sole species consisting of the seven foregoing subspecies with a change of subspecies *choleraesuis* to subspecies *enterica*.[406] The type strain was also changed from *S. choleraesuis* to *S. enterica* subspecies *enterica* serovar Typhimurium LT 2. In 1989, the subspecies *bongori* was elevated to species level based on discriminating multilocus enzyme electrophoretic patterns.[548] The *Salmonella* genus presently consists of two species: *S. enterica* including six subspecies (*enterica, salamae, arizonae, diarizonae, houtenae,* and *indica*) and *S. bongori*. No fewer than 2,422 serovars are recognized within the genus (Table 45–1). All name-bearing serovars belong to subspecies *enterica* whereas serovars in the remaining subspecies of *S. enterica* and in *S. bongori* are identified by antigenic formulae.

45.3 CHARACTERISTICS OF DISEASE

45.3.1 Clinical Symptoms and Treatment

The clinical presentation of human salmonellosis may correspond to either the enteric fever syndrome following infection with typhoid or paratyphoid strains or to the nontyphoid-dependent gastroenteritis/enterocolitis with possible progression to a more serious systemic infection. Humans are particularly vulnerable to *S.* Typhi and *S.* Paratyphi A, B, and C infections because of the ability of these strains to invade and multiply within host tissues. Enteric fever can result from exposure to an infected individual or from contact with contaminated food and water. Clinical symptoms appear 7 to 28 days following exposure to these serovars. Watery diarrhea or, infrequently, constipation, persistent and spiking fever, abdominal pain, headache, nausea, prostration, and a rash of rose spots on the shoulders, thorax, or abdomen may occur. Complications of enteric fever include intestinal bleeding from ileal ulcers or intestinal perforation resulting from hyperplasia of the epitheliolymphoid Peyer's patches. Clinical diagnosis of the disease commonly is based on symptomology and isolation of the causative agent from blood samples during the first 2 weeks of illness. Stool and urine samples are less dependable. Isolation from bone marrow can be valuable, particularly with patients who are already undergoing antibiotic treatment.[111,440,711] Enteric fever may be identified by the Widal immunological test whereby antibodies in the sera of patients agglutinate with *S.* Typhi somatic and flagellar antigens.[131] Enzyme-linked immunosorbent assays (ELISA) for the detection of Vi- or lipopolysaccharide-specific antibodies in human serum have also been proposed.[440] Encouraging results were recently obtained with a Vi antigen-specific DNA probe for the detection of *S.* Typhi in infected blood.[569] Clinical management of human typhoid and paratyphoid infections rests on an aggressive course of antibiotic therapy. Although chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole (SXT) once constituted the mainstay of treatment, the emergence and persistence of strains resistant to these drugs notably in Asia and Central and South America[515,563,568,711] has resulted in the use of cephalosporins and fluoroquinolones.[48,285,442,563,617] Between 1.0% and 5.0% of typhoid patients become chronic fecal carriers after the remission of clinical symptoms,[111,285] but prolonged treatment with fluoroquinolones such as ciprofloxacin and norfloxacin can significantly reduce the rate of chronic carriage.[48,285]

Table 45–1 Distribution of Serovars within the *Salmonella* Genus[523]

Species	*Subspecies*	*Number of Serovars*
S. enterica	*enterica*	1,427
	salamae	482
	arizonae	94
	diarizonae	319
	houtenae	69
	indica	11
S. bongori		20
Total		2,422

Source: Data from M.Y. Popoff, J. Bockemuhl, and F.W. Hickman-Brenner, Supplement 1995, No. 39, to the Kauffmann-Wite Scheme, *Research in Microbiology*, Vol. 147, pp. 765–769, © 1996.

The symptoms of nontyphoid salmonellosis may include nausea, abdominal cramps, diarrhea with watery and possibly mucoid stools tinged with blood, fever of short (<48 hours) duration, and vomiting that appear 8 to 72 hours following exposure to the bacterium.[333,711] Isolation of the causative agent from stools or other infected sites confirms salmonellosis. The treatment of *Salmonella* enterocolitis with antibiotics generally is contraindicated because it tends to prolong the excretion of the microorganism in stools and does not alter the normal course of the disease. Fluid and electrolyte replacement may be indicated for severe cases of diarrhea. The clinical symptoms of uncomplicated enterocolitis usually subside within 5 days followed by a convalescent carrier state of one to several months during which the asymptomatic individual continues to excrete salmonellae. Personal hygiene during this period is critical if cross-infection in the home or workplace is to be avoided. Enterocolitis does not lead to acquired immunity and re-exposure to nontyphoid salmonellae will most likely result in disease. Nontyphoid salmonellosis can progress from an enterocolitic to a septicemic condition because of the migration of salmonellae from the intestinal tract into deeper tissues through vascular and lymphatic conduits. Although stool cultures generally are negative at this stage, blood samples will frequently yield salmonellae. Systemic spread of the pathogen can lead to cardiac and circulatory anomalies, intracranial infection, and dysfunction of major body organs.[135,182,299,383,562] Fluoroquinolones are being used increasingly for the treatment of septicemic conditions.[48,392,530,587] Several important chronic sequelae can also be associated with nontyphoid salmonellosis and other enteric infections (Chapter 55). These include arthropathies such as aseptic reactive arthritis (RA), Reiter's syndrome, (RS), ankylosing spondylitis (AS), and rheumatoid arthritis as well as human deficiencies in nutrition and intestinal absorption.[42] There is an apparent genetic predisposition of individuals carrying the human leucocyte antigen (HLA) B27 gene within the chromosomal major histocompatibility complex (MHC) class I locus to the development of RA, RS, or AS several weeks after the acute phase of nontyphoidal salmonellosis.[107,581,615,644] The RA and RS conditions share clinical features such as inflammation of articulated joints of upper and lower limbs, conjunctivitis, and urethritis and frequently progress to AS as evidenced by the inflammation of vertebrae.[107,615] These pathologies develop and persist in the absence of an active *Salmonella* infection and in the absence of viable microorganisms in the inflamed anatomical regions. One hypothesis concerning the relationship between the predisposing human HLA-B27 genotype and the host-pathogen interactions culminating in arthritides suggests a cross-reactivity of antibody to *Salmonella* antigen(s) and HLA-B27 antigens located on the surface of host nucleated cells. Following the immunological clearance of the invasive salmonellae, circulating antibodies specific to the infectious strain bind to the human HLA-B27 antigen. This leads to an arthritic autoimmune disorder in which reactions between synovial T-lymphocytes and HLA-B27 antigen-antibody complexes produce chronic inflammation of the affected joints.[107,615] The ability of antibodies to nonarthritogenic bacteria to recognize the HLA-B27 antigen questions the reliability of the cross-reactivity hypothesis. Another putative mechanism relates to the ability of salmonellae to alter the host HLA-B27 antigen to a state that host T-lymphocytes will recognize as a foreign antigen, thereby triggering an arthritic inflammatory response.[262] The failure of other workers to corroborate these preliminary experimental findings undermines the acceptance of this theory.[107] Other HLA-B27 independent mechanisms for RA have been proposed. The chemical degradation and release of *Salmonella* lipopolysaccharides (LPS) by host phagocytes followed by the incorporation of the degraded LPS into host cell membranes could potentiate an autoimmune response involving LPS-presenting host cells and natural immunological processes.[107,287] Stress proteins produced by bacterial and host cells as a protective response to adverse environmental conditions are highly conserved[261,615,696,712] and may be involved in the induction of reactive arthritides. This suggests that the activation of T-lymphocytes against *Salmonella* stress proteins could trigger a concurrent autoimmune response from a lymphocyte recognition of host stress proteins on the surface of synovial cells. Contradictory reports on the importance of stress proteins in the development of RA underline the need for further research in this area of *Salmonella* pathogenesis.

45.3.2 Prophylactics

The development of human parenteral heat-inactivated, phenol-preserved whole cell typhoid and paratyphoid vaccines at the close of the nineteenth century contributed significantly to the reduction of enteric fever in endemic areas.[414,440] These vaccines confer 80% to 90% protection for 3 to 7 years and are associated with low to moderate levels of adverse reactions. The preparations stimulate serum antibody production but are poor inducers of cell-mediated and local secretory immune (s IgA) responses.[675] An oral typhoid vaccine manufactured by the Swiss Serum and Vaccine Institute (Berne) under the trade name Vivotif Berna consists of three enteric-coated capsules each taken on alternate days. The treatment provides 60% to 80% protection for up to 7 years with booster doses recommended at 3-year intervals.[675] The vaccine *S.* Typhi Ty21a strain was originally derived from random mutagenesis with nitrosoguanidine and ultraviolet light irradiation.[267] The mutant lacks the Vi surface antigen and contains a mutation in the galactose epimerase (*gal E*) locus, which prevents the synthesis of complete LPS.[122,210] The latter condition results in a rough variant that is highly susceptible to lysis by the host complement system.[162] Although the *gal E* mutation putatively formed the basis for strain attenuation, subsequent studies failed to support this hypothesis.[112] The Ty21a strain harbors a mutation in the genomic *rpoS* locus that normally encodes protective proteins under environmental stress conditions and that likely contributes to strain attenuation.[560] Another recently marketed typhoid vaccine uses the Vi capsular polysaccharide as immunogen. This injectable preparation is distributed by the Pasteur Mérieux Sérums et Vaccins (Lyon, France) under the trade name Typhim Vi. A single dose of this phenol-preserved antigen produces low to moderate levels of secondary reactions and confers protection for up to 3 years.[382]

The clinical success of the oral Ty21a and the injectable Vi vaccines has not dampened research interests in the development of novel typhoid and paratyphoid vaccines providing high levels of immunogenicity, biological safety, and storage stability and engendering few side effects. The use of attenuated strains of *S.* Typhi as potential immunogens has been investigated because of the ability of viable but avirulent and nonreverting typhoid mutant strains to induce strong humoral and cell-mediated responses. Auxotrophic mutant strains that are blocked in essential biosynthetic pathways (*aro*, *pur*, *his*) or typhoid mutants that are deficient for adenylate cyclase and the cyclic adenosine monophosphate (cAMP) receptor protein (*cya*, *crp*) are promising genetically defined variants.[112,122,153,154] The recently characterized typhoid strain incapable of growth at temperatures greater than 29° C may prove useful as an oral vaccine.[66] The favorable evaluation in humans of an oral typhoid vaccine based on an *S.* Typhi Ty2 strain harboring deletion mutations in *aro C* and *aro D* (designated CVD 908) may culminate in the marketing of a novel single-dose oral typhoid vaccine.[332] An injectable semisynthetic Vi vaccine has been synthesized consisting of vegetal pectin acetylated in the C2 and C3 positions and conjugated to tetanus toxoid.[630] The acetylated pectin is a lower molecular weight homolog of the Vi antigen and is nonimmunogenic in mice. The injection of mice with one or two doses of tetanus-pectin conjugate produced greater serum levels of Vi-specific antibodies than those obtained with purified Vi antigen alone. Future trials on the efficacy of conjugated pectin as a parenteral typhoid vaccine clearly are indicated. Although highly desirable, the development of nonviable *Salmonella* oral vaccines has met with limited success because of a need for oral immunogens that resist degradation by gastric acidity and digestive enzymes and trigger a specific immune response at the surface of the intestinal mucosa.[210] Encapsulation of immunogens in acid-resistant and biodegradable materials may resolve this problem.[485] Notwithstanding the success of nonviable oral vaccines against cholera and *E. coli* enterotoxins in stimulating mucosal immunogenicity, a similar *Salmonella* vaccine has not yet been developed.[210]

There is interest in the development of nontyphoidal vaccines for humans and farm animals. The great diversity and rapid temporal succession of serovars in the environment and in the global food chain, and the heterogeneity of immunogenic bacterial surface organelles continue to hamper the development of effective *Salmonella* vaccines. Live vaccine constructs are based on genetic mutations that render viable salmonellae avirulent without adversely affecting their immunogenicity. Although the *gal E* mutation successfully attenuated *S.* Typhimurium and *S.* Enteritidis, it failed to curtail the virulence of *S.* Typhi and *S.* Choleraesuis.[154,331] Clearly, the use of the *gal E* lesion alone is of limited value in vaccine development. Strain attenuation by deletion mutations in the purine (*pur*) genes led to similarly unfavorable conclusions.[114] Transposon mutagenesis in *aro* genes of the aromatic pathway results in auxotrophy and strain attenuation resulting from an inability to synthesize essential compounds such as p-aminobenzoic and dihydroxybenzoic acid, precursors of folic acid and the iron chelating enterochelin, respectively. The nonavailability of these metabolic precursors in host tissues prevents the proliferation of the autotrophic mutant in host cells. *Aro* mutants have found wide application in oral and parenteral vaccines for humans and animals including cattle, sheep, and poultry.[122,138,154,613] Deletions in the adenyl cyclase (*cya*) and the cAMP receptor protein (*crp*) genes lead to attenuated strains that trigger strong and durable immunological responses in orally vaccinated animal models.[154] Mutant strains harboring a single deletion in *cya* or *crp* can revert to the parent genotype, whereas strains with double deletions are quite stable.[114] The vaccine potential of other mutations such as deletion in the *pho P* and *pho Q* genes encoding protective proteins for the survival of *Salmonella* in host macrophages, deletion in the *cdt* locus that potentiates bacterial invasion of deep tissues, curing of virulence (*spv*) plasmids, and lesions in the outer membrane protein regulator (*omp R*) gene continue to attract research interest.[59,114,122,154,210]

Another important facet of vaccine development has been the construction of viable and attenuated *Salmonella* mutants for the delivery of heterologous antigens. Prerequisites for effective and safe recombinant *Salmonella* vectors include avirulence, strong immunogenicity, and a minimum of two stable, nonreverting attenuating deletion mutations.

Although plasmid vectors carrying a foreign gene have figured prominently in developmental research on hybrid *Salmonella* vaccines, problems of vector stability in carrier strains have shifted research interests toward a more stable incorporation of foreign antigens into the *Salmonella* chromosome.[122] However, the latter approach suffers from a potentially low immunogenic response owing to the insertion of a single gene copy into the *Salmonella* chromosome. This is in sharp contrast to the use of multiple plasmid-inserted gene copies in a single *Salmonella* carrier cell. Notable developments have included a bivalent oral typhoid-tetanus vaccine derived from the insertion of the tetanus fragment C toxin gene into the chromosome of a live attenuated *aro A* and *aro C* strain of *S.* Typhi Ty2. Preliminary human trials with this preparation are imminent. The same research group is also developing a more potent human typhoid-tetanus oral vaccine wherein the fragment C gene is carried on a plasmid vector whose expression is under the control of an inducible *nir B* promoter that not only confers stability to the plasmid vector, but also directs a high level expression of the tetanus toxin gene.[122] Attenuated typhoid and nontyphoid vaccines have been developed also for the delivery of foreign antigens such as the form I somatic antigen of *Shigella sonnei*,[666] the binding subunit of the heat-labile toxin (LT-B) of enterotoxigenic *Escherichia coli*,[132] the somatic antigen of *Vibrio cholerae* serotype Inaba,[631] and the hepatitis B and papillomavirus specific antigens[395,588] to mammalian immune systems.

45.3.3 Incidence of Human Salmonellosis

Recent reports from international sources continue to underline the importance of *Salmonella* spp. in human diarrheal disease and in focal and systemic infections. Contributing factors may include contact with an infected individual, exposure to a contaminated environment, or the ingestion of foods containing this microorganism.[162,166] The reported incidence of human salmonellosis varies widely among countries [Table 42–2] and likely stems from the endemicity of the disease in certain countries and from inequalities of national health reporting systems and in the containment of outbreaks. Dramatic increases in the reported rates of human *Salmonella* infections in continental Europe, notably Denmark, Italy, and Lithuania, are disquieting. The reason(s) for the unusually high rate of human *Salmonella* infections in the former Czech Republic are uncertain.

Table 45–2 Reported Incidence of Human Salmonellosis

Country	*Period*	*Rate**	*Reference*
Austria	1989	62.0	266
Bulgaria	1992	25.2	705
Canada	1993	29.7	308

* Rate per 100,000 population.

Newborns, the elderly, and immunocompromised individuals are particularly susceptible to bacterial infections in general and to salmonellae in particular.[30,205,705] Hospital nurseries and neonatal intensive care units are particularly vulnerable to the rapid spread of *Salmonella* infection following the admission of an infected infant.[46,301,457,626] Infections can develop from the frequent contact between the nursing staff and the patients, invasive clinical procedures such as catheterization, intubation, and thermometry, and from the creation of aerosols in poorly ventilated hospital units.[626] Nursing homes and geriatric hospital wards are equally prone to the rapid spread of *Salmonella* among residents and support staff, with a propensity for clinical complications and death of elderly patients.[149,370,621] Although young and mature adults are more resistant to *Salmonella* infections, strain virulence, infectious dose, underlying ailments, prophylactic or therapeutic drug treatments before exposure to invasive salmonellae, achlorhydia arising from gastric resection or metabolic dysfunction, and the nature of an ingested contaminated food can facilitate the entry and persistence of the bacterium in the gastrointestinal tract.[160,166] The view that all *Salmonella* serovars are potentially pathogenic to man is reinforced by reports of disease from members of subspecies other than subspecies *enterica* that more commonly occur in poikilothermic animals and in the natural environment[405] and from the presence of key virulence factors in exotic serovars.[203] Domestic reptilian pets are well documented as reservoirs of exotic serovars and as sources of salmonellosis in children.[2,174,584,702] Evidence that the disease can degenerate readily into chronic and debilitating clinical conditions condemns any complacency in maintaining the highest level of sanitation in homes and in health care facilities.

Although *S.* Typhimurium has consistently dominated national reports of human salmonellosis prior to the mid-1980s,[160] the ongoing pandemic of *S.* Enteritidis, attributed primarily to the transovarian transmission of this invasive serovar in commercially reared chickens, has dramatically altered the statistics of human *Salmonella* infections in recent years. *S.* Enteritidis is now the most common cause of human salmonellosis in many European countries—notably England and Wales,[206] Spain,[665] Scotland,[600] Italy,[592] and France.[291] Factors that may contribute to the introduction of new serovars include importation of contaminated foods and food ingredients from countries with inadequate hygienic controls, return of travelers infected abroad with exotic *Salmonella* serovars, selection of resistant serovars due to the widespread use and abuse of antibiotics in human medicine and in agricultural and aquacultural food production, seasonal migration of birds and other wildlife, and the unrestricted movement of contaminated surface waters. The following episodes exemplify the important role of international food trade in the dissemination of uncommon *Salmonella* serovars. Cocoa beans imported from Africa were incriminated in a major chocolate outbreak of *S.* Eastbourne in Canada and the US. This serovar, which rarely had been encountered in either country previously, virtually disappeared after the outbreak.[146,164,177] An outbreak in England and Wales associated with importation of Italian chocolate contaminated with *S.* Napoli also subsided without entrenchment of the bacterium in the environment or in the food chain.[495] The inability of uncommon serovars to establish themselves in human populations and/or the food chain may result from the effective containment and treatment of infected human cases, thereby preventing further dissemination of the bacterium, or from its competitive exclusion by natural endogenous microflora in potentially suitable ecological niches.

45.3.4 Antibiotic Resistance

The increasing occurrence of antibiotic-resistant *Salmonella* spp. has compromised the therapeutic efficacy of first-line antimicrobial drugs such as ampicillin, chloramphenicol, and trimethoprim sulfamethoxazole for the treatment of typhoid and paratyphoid fever.[296,515,568,651] Failure to effectively deal with this growing human health threat could result in the widespread contamination of the global food supply with multiple antibiotic-resistant salmonellae and other bacterial pathogens. The public health concern for the growing prominence of resistant *Salmonella* is heightened by the propensity for the conjugative transfer of resistance (R) plasmids.[166] Linked resistance whereby a single R-plasmid encodes resistance to multiple antibiotics is a problem in both human and veterinary medicine. In recent years, treatment in the UK of a septicemic patient infected with *S.* Typhimurium DT 104 with ampicillin could prove unsuccessful and select for strains that carry a 60 megadaltons plasmid-encoded multiple resistance to ampicillin (A), chloramphenicol (C), streptomycin (S), sulphonamides (Su), and tetracycline (T). The R-type ACSSuT of *S.* Typhimurium, which was first recognized in the UK in 1984, is progressively acquiring resistance to trimethoprim and ciprofloxacin.[677] This phenotype is now the second most common *Salmonella* isolated from humans in England and Wales, overshadowed only by *S.* Enteritidis PT4. The prevalence of R-type ACSSuT in the US also has increased sharply in recent years and accounted for 32% of all human *S.* Typhimurium isolates in 1996.[37]

The high resistance of *S.* Typhimurium to A, C, trimethoprim and SXT in most of the listed countries contrasts sharply with the generally lower level of resistance encountered with other serovars (Table 45–3). The acquisition of such resistance probably resulted from the continued prominence of *S.* Typhimurium in human disease and the widespread use of A, C, and SXT in the treatment of bacterial infections. It will be interesting to follow whether the gradual abandonment of A, C, and SXT in human medicine in favor of newer drugs such as third-generation cephalosporins and fluoroquinolones will result in a marked reduction in the resistance of *Salmonella* to A, C, and SXT. The recent introduction of ciprofloxacin and other fluoroquinolones for the treatment of systemic salmonellosis and the chronic *Salmonella* carrier state may have fostered the emergence of ciprofloxacin-resistant *S.* Typhimurium and *S.* Enteritidis in England and Wales and in the US, respectively. The increased ciprofloxacin resistance of *S.* Hadar from 2.0% to 39.6% between 1991 and 1994 in England warrants close monitoring.[247] Ofloxacin resistances of ≤7.0% in human *Salmonella* isolates were reported in France,[98] Hong Kong,[375] and India,[466,682] whereas 56.8% of 73 strains of *S.* Typhimurium in Brazil were resistant to pefloxacin.[45] Nalidixic acid resistance was reported in 93.0% of human *S.* Typhimurium isolates in India[682] and in 100% of *S.* Hadar isolates in Belgium.[518] Resistance of *Salmonella* spp. to two or more antibiotics is not uncommon, and several human *Salmonella* isolates in Korea were shown to be resistant to 10 antibiotics.[120] National 2- to 25-fold increases in the number of human *Salmonella* isolates resistant to A and C in recent years cast a bleak prospect for the future (Table 45–4). Less dramatic changes in resistance were reported for trimethoprim (Tp) and SXT in most countries, whereas increases in multiple resistance were generally modest except for Spain where a 31-fold increase was reported for the period 1986 to 1991. From 1981 to 1990, the resistance of bovine isolates of *S.* Typhimurium to A, C, Tp, and multiple antibiotics increased significantly in England and Wales.

The current situation has developed partly from the use and abuse of antibiotics in human medicine and from the continuing widespread use of medically important antibacterials as growth-promoting or prophylactic agents in the agriculture and aquaculture (Section 45.5.2).

45.4 MECHANISM OF PATHOGENICITY

45.4.1 Dynamics of Invasion

Nonspecific host defenses play an important role in averting bacterial infection from the consumption of *Salmonella*-contaminated foods. These constitutive protective mechanisms include antibacterial lactoperoxidase in the human saliva, gastric acidity, intestinal mucoid secretions, peristalsis, and sloughing of enterocytes that synergistically oppose the *Salmonella* colonization of the intestinal mucosa. These natural hurdles are reinforced immunologically by the bactericidal action of epitheliolymphoid tissues (Peyer's patches), phagocytic leucocytes such as monocytes, macrophages, and polymorphonuclear leucocytes and by the lytic activity of host complement and T-lymphocytes.[166] Prerequisites for a successful human *Salmonella* infection include the attachment (colonization) to mucosal enterocytes or to the specialized M cells in Peyer's patches of the small bowel. The subsequent penetration of salmonellae into the cytoplasm of epithelial cells triggers an influx of leucocytes to the infected area and a leucocytic release of prostaglandin resulting in mucosal inflammation. The bacterial release of enterotoxin within the inflamed tissues activates host adenyl cyclase resulting in a diarrheagenic fluid secretion into the intestinal lumen.

Determinants for the invasion phenotype of *Salmonella* are encoded by no fewer than 28 genes located in a contiguous 35 to 40 kb region at centisome 63 (pathogenicity island) of the *Salmonella* chromosome. The low G + C content of this region compared with that found in the remaining chromosomal DNA suggests that the entry genes were acquired in block by horizontal transfer from another microorganism. The invasion region of the chromosome corresponds to a contact-dependent type III secretion system for the delivery of bacterial proteins involved in the invasion of targeted eukaryotic cells.[248] The loci for invasion (*inv*), the surface presentation of antigen (*spa*), the *Salmonella* invasion protein (*sip*), the *pho P* repressed gene (*prg*), the hyperinvasive locus (*hil*), and the oxygen-regulated gene (*org*) figure prominently in this protein export system. Ambient osmolarity and oxygen tension modulate the bacterial expression of the *inv* locus by

altering the helicity of chromosomal DNA and the transcription of genes within the pathogenicity island.[250] Surface contact between invasive salmonellae and the microvilli of enterocytes engenders the bacterial formation of transient proteinaceous appendages that are deemed essential for *Salmonella* invasion.[275] These appendages, termed invasomes, are much thicker than flagella and type-1 fimbriae and measure 0.3 to 1.0 μm in length and approximately 60 nm in diameter.[250] The infrastructure and role of invasomes remain elusive.[249] Several *inv* loci are linked functionally in the energy-dependent assembly of these surface organelles.[136] A synthetase enzyme encoded by the *inv I* locus together with an uncharacterized gene product from the *inv J* locus provide the building blocks for the bacterial appendages, which are exported to the cell exterior by an *inv G*-encoded translocase driven by an *inv C*-encoded ATPase.[166]

The next event in *Salmonella* invasion involves bacterial signals that induce the polymerization of actin and cytoskeleton rearrangement within the enterocyte cytoplasm and the formation of membrane ruffles or blebs on the surface of intestinal epithelial cells and of M cells in Peyer's patches. Ultimately, the membrane ruffles engulf and draw the adherent *Salmonella* cells into the enterocyte cytoplasm by macropinocytosis.[246] These Ca^{+2}-dependent events are elicited by signal transduction from the invading microorganism where the high enterocyte Ca^{+2} concentration required for actin polymerization derives from two independent mechanisms. The release of bacterial gene products encoded by the genomic *inv E* locus produces a net influx of lumenal Ca^{+2} into the host cell cytoplasm.[276] The signal transduction for Ca^{+2}-dependent entry into host cells is also linked to the *Salmonella*-induced phosphorylation of tyrosine in host mitogenic activating protein kinase and in the epidermal growth factor receptor.[249,566] The identity of the *Salmonella* inducer is uncertain. The second mechanism that contributes to the high Ca^{+2} concentration in enterocytes relates to a *Salmonella* induction of host phospholipase C activity, resulting in the breakdown of enterocyte membrane lipids and intracytoplasmic release of inositol triphosphate that liberates cytoplasmically bound Ca^{+2}. The appearance of host cell ruffles coincides with the disappearance of the surface appendages on adherent salmonellae. The *Salmonella* invasion gene (*sip*) encodes the important Sip B, C, and D secretory proteins for bacterial entry into host cells. Although their mechanisms of action have yet to be confirmed, formation of transmembrane channels in the mammalian cell may be involved.[249]

Salmonellae are internalized within pinocytotic vacuoles whose membranes predominantly contain MHC class 1 proteins.[246] These MHC proteins originating from a *Salmonella*-directed aggregation of enterocyte membrane proteins putatively conceal the presence of an infected vacuole from immunological host defenses.[255] The reversion of actin microfilaments and membrane ruffles to their basal states coincides with the formation of endocytic vacuoles. Further maturation of the infected vacuole results in a decrease in membrane MHC 1 proteins in favor of lysosomal glycoproteins, which may protect against the degradative action of host cell enzymes.[254] In contrast to *Yersinia*, *Shigella*, and enteroinvasive *E. coli* that replicate within the cytoplasm of host cells, *Salmonella* multiply within vacuoles.[253] The concurrent appearance of filamentous structures containing acid phosphatase and lysosomal membrane glycoproteins that seemingly link the infected vacuole to the epithelial cytosol was recently described. The formation of these organelles of unknown function requires viable salmonellae within endocytic vacuoles.[256] The infected vacuoles translocate from the apical pole to the basal membrane of the host cell where salmonellae are released into the lamina propria. The binding of host plasminogen and its specific activator to *Salmonella* fimbriae and subsequent conversion to proteolytic plasmin may enable salmonellae to permeate host tissue barriers and migrate into deeper host tissues.[610]

45.4.2 Virulence Factors

In addition to the genomic *inv*, *sip*, *hil*, and *prg* loci that facilitate bacterial invasion of host cells, other virulence factors potentiate the survival and/or growth of *Salmonella* in the hostile mammalian host environment. The expression of many genes encoding virulence determinants is triggered by a variety of host-dependent signals.

Iron is essential for the maintenance of mammalian cells and for the growth and survival of salmonellae.[148] The finite amount of cationic iron available in mammalian tissues leads to strong competition between both cellular antagonists. The host transferrin- and lactoferrin-dependent sequestering of iron and subsequent intracellular storage of captured iron as ferritin-iron (III) complexes potentially is bacteriostatic. *Salmonella* rely on two iron-scavenging siderophores chromosomally regulated by the *fur* gene to satisfy their requirement for this cation.[166] The high affinity of the phenolate siderophore termed enterochelin or enterobactin enables it to dislodge and sequester ferric ions previously bound to mammalian iron-binding proteins.[436] A lower affinity hydroxamate aerobactin also competes with host chelators for ferric cations. The bacterial uptake of ferric-siderophore complexes is mediated by an outer membrane protein (OMP) receptor previously induced by iron depletion in the bacterial cell. The cytoplasmic internalization of the ferric-siderophore complex coincides with a reduction in the oxidative state of the internalized complex. Consequently, ferrous ions are released into the bacterial cytoplasm because of the low siderophore affinity for iron (II) cations. The decreased virulence of salmonellae under conditions of iron deprivation underlines the importance of bacterial siderophores in pathogenesis.[436]

Salmonellae are responsive to marked changes in the osmolarity, temperature, oxygen tension, oxidative stress, and low nutrient levels in their microenvironment. The *omp R* and *env Z* genomic loci constitute a two-component system that regulates the synthesis of the Omp C and Omp F transmembrane porins in response to prevailing osmolar conditions. The Omp R transcriptional regulator is activated by signal transduction from the inner membrane Env Z sensor. The importance of this system in pathogenicity is evidenced by the attenuation of strains carrying a mutation in *omp R* or a double mutation in the *omp C* and *omp F* loci. A mutation in either porin locus does not affect the virulence of carrier strains.[209] The rapid synthesis of heat-shock proteins in prokaryotic and eukaryotic cells is induced by stress conditions such as major upshifts in temperature, extreme pH values, and presence of toxic products from the oxidative burst of phagocytes. These proteins function as molecular chaperones or as proteases.[292] Chaperones ensure that newly synthesized proteins are assembled into an active configuration, whereas proteases degrade abnormal or dysfunctional peptides. The highly discriminating and corrective functions of heat-shock proteins attest to their importance in the survival of *Salmonella* during its infectious cycle. The oxygen tension in the microenvironment can also induce the expression of invasion genes. Low levels of oxygen, presumably similar to that found in the intestinal lumen, increased the invasiveness of *S.* Typhimurium into cultured mammalian cells, whereas growth under high oxygen tension markedly reduced invasiveness.[436] The systemic migration of salmonellae in the host exposes the microorganism to phagocytosis by macrophages, monocytes, and polymorphonuclear leukocytes and to the antibacterial conditions within these host defense cells.[162,166] The toxicity of singlet oxygen, superoxide anion, hydrogen peroxide, and hydroxyl radicals generated during the oxidative burst of phagocytes is minimized through the degradative actions of bacterial superoxide dismutase, peroxidase, and catalase enzymes and by the cytotoxic product-dependent induction of the *oxy R* locus that regulates the synthesis of protective proteins.[166,522] The resistance of *oxy R* mutants of *S.* Typhimurium to phagocyte inactivation does not support the protective role putatively ascribed to the *oxy R*-dependent proteins.[501] The chromosomal *rpo S* locus is induced under conditions of nutrient deprivation as encountered in the infected phagosomes of host macrophages or in salmonellae entering the stationary phase of growth. The alternative sigma factor (σ^s) encoded by the *rpo S* gene couples with core RNA polymerase to form the holoenzyme.[402] The proper alignment of the polymerase holoenzyme with its targeted gene encoding a protective protein derives from the σ^s-dependent recognition of a specific promoter sequence in the targeted gene. The σ^s factor thus identifies the DNA domain where gene transcription begins. The transcription of numerous genes and operons is under σ^s control.[427]

An important facet of acid resistance in *Salmonella* relates to the genomic *phoP/phoQ* regulon that facilitates the survival of salmonellae within the acidic environment of phagocytes. This two-component transcriptional regulator system also protects against the lytic action of nonspecific cationic peptides (defensins) produced by phagocytes and epithelial cells.[166,460,673] The gene product of the *pho Q* locus is a kinase that senses unfavorable acidic conditions in the cell exterior by means of a short amino acid sidechain that extends into the periplasmic space of the bacterial cell envelope. The sensorial attributes of Pho Q are due, apparently, to acidic amino acid residues in the sidechain (anionic box) and their putative ability to recognize cationic defensins and the high proton concentration in the phagocyte cytoplasm. The activated kinase then relays the environmental signal through autophosphorylation and a kinase-dependent transfer of phosphate to the *phoP* transcriptional activator protein.[460] The phosphorylated PhoP subsequently activates the transcription of 18 genes, including the *pagA* to *pagP*, *psi D*, and *pho N* loci. The gene products of these loci do not confer protection against defensins; however, the *pag C* gene encodes a virulence-determining OMP that protects against the lytic attack of serum complement, whereas the gene products of the *pag D, pag J, pag K,* and *pag M* loci enhance *Salmonella* survival in macrophages.[65] In contrast to *phoP*-activated gene (*pag*) loci, which are induced in response to unfavorable environmental conditions, *phoP*-repressed genes (*prg*) are expressed under nonstress conditions and collectively encode about 20 proteins involved in bacterial invasion of epithelial cells, increased pinocytosis, membrane ruffling, or formation of spacious phagosomes in macrophages.[64,166]

Virulence plasmids play an important role in the pathogenicity of *Salmonella* spp. These cytoplasmic DNA organelles occur in low copy numbers and replicate independently of the bacterial chromosome. They occur in a limited number of serovars and, surprisingly, are absent in typhoid and paratyphoid strains.[162,293] *Salmonella* virulence plasmids vary from 30 to 60 MDa in size and contain highly conserved nucleotide sequences (structural homology) capable of restoring the virulence of plasmid-cured strains (functional homology). However, the conjugative transfer of plasmids between *Salmonella* strains occurs infrequently as suggested by the remarkable similarity of virulence plasmids within a given serovar and marked differences between plasmids of different serovars.[294] Virulence plasmids encode factors that promote the systemic spread of salmonellae in host tissues and the bacterial proliferation in macrophages.[295] A highly conserved 6.4 to 8kb region figures prominently in *Salmonella* virulence plasmids.[629] The transcription of this genetic locus, termed *Salmonella* virulence plasmid (*spv*), is induced on bacterial exposure to acidic conditions within phagocytes and other microenvironments, elevated temperatures, and nutrient deprivation.[634] The *spv* operon consists of five open reading frames corresponding to a regulator gene (*spv R*) and a cluster of four structural genes (*spv ABCD*). One of the two promoter regions within the *spv* operon lies upstream from *spv R*, whereas the second promoter is positioned between the *spv R* and *spv A* loci.[295] Transcription of the *spv ABCD* gene cluster progresses sequentially from left to right under the combined control of the *spv R* regulator protein and the alternate sigma factor (σ^s) encoded by the *rpo S* locus.[123,394] The yield of gene products from the transcription of the *spv A* to *spv D* loci occurs in decreasing amounts and is greater in stationary than in log phase cells.[294] The σ^s is the principal activator of the *spv R* locus through its interaction with the *spv R* promoter region, and overshadows the minor involvement of Spv R as a self-regulator of the *spv R* locus.[123,310] The role of the *spv ABCD* gene products in conferring strain virulence is poorly understood. Transposon insertion experiments with *S.* Dublin recently demonstrated that *spv R* and *spv B* are essential virulence genes, whereas *spv C* and *spv D* played a secondary but necessary role for the development of full strain virulence. The *spv A* locus reportedly did not contribute to strain virulence.[294] In contrast, a 10-fold greater expression of *spv A* in *S.* Dublin than in *S.* Typhimurium was tentatively associated with the high virulence of *S.* Dublin.[634] Other genetic determinants that enhance bacterial pathogenicity also occur on *Salmonella* virulence plasmids.[293] These include the resistance to complement killing (*rck*) locus whose gene product blocks the formation of a functional C5b-9 complement membrane attack complex and prevents its lytic insertion into the bacterial outer membrane. The plasmidic replication (*rep*) and stability (*par, rsd, crs*) loci that ensure stable plasmid maintenance are not uniformly distributed among serovars that carry virulence plasmids.

Several bacterial surface structures contribute to the virulence of *Salmonella* spp. A polysaccharide capsular antigen designated Vi occurs in *S.* Typhi and *S.* Paratyphi C but rarely in *S.* Dublin.[522] The Vi capsule inhibits the binding of the C3b host complement factor to the bacterial LPS, a prerequisite for the complement lysis of salmonellae and induction of macrophage phagocytosis.[162] The length of LPS on the bacterial surface also affects complement lysis. In smooth variants, the long LPS sterically hinders the stable insertion of the C5b-9 lytic complex into the outer membrane. Rough strains with a short LPS lack this protective attribute. It follows that smooth variants exhibit greater virulence than rough *Salmonella* strains. Therefore, the Vi capsular antigen, the plasmidic *rck* locus, and the surface LPS play an important role in bacterial resistance to host complement lysis. The previously discussed Omp C and Omp F outer membrane porins are equally important surface structures because they potentiate greater tolerance to wide osmolar fluctuations in the bacterial microenvironment (Section 45.4.1).

Several toxins, including endotoxin, enterotoxin, cytotoxin, *zot* (zonula occludens toxin)-like protein, and salmolysin, are associated with *Salmonella* spp.[660] The endotoxin consists of three molecular domains: an outer hexose polysaccharide chain that provides for the serotypic differentiation of strains, a core polysaccharide chain consisting of hexose (outer) and heptose (inner) units, and an innermost lipid A moiety that triggers the endotoxic response in infected hosts. The cryptic positioning of lipid A within the bacterial outer membrane hampers the induction of host inflammatory reactions pending the lytic release of lipid A into host tissues. On release, lipid A activates the leucocytic production of cytokines that trigger the inflammatory response. Endotoxins released in host cells also can induce the expression of host surface receptors that can serve as enterotoxin binding sites. Most strains of *Salmonella enterica*, but none belonging to *Salmonella bongori*, possess the enterotoxin gene (*stn*). This locus is located on a 2.8 kb DNA segment that maps at 89.7 minutes on the chromosome and encodes a 29 kDa thermolabile protein. *Salmonella* enterotoxin induces the elongation of Chinese hamster ovary (CHO) cells but fails to alter the morphological integrity of Y-1 adrenal and HeLa cell monolayers. The cytotonic enterotoxin does not share any nucleic or amino acid homology with cholera toxin nor with the thermolabile enterotoxin (LT) of *Escherichia coli.*[660] The ability of cholera antitoxin to neutralize *Salmonella* enterotoxin remains controversial.[126,541,660] Serological and electrophoretic pattern studies suggest that the *Salmonella* enterotoxin consists of A (active) and B (binding) subunits. The A moiety activates host cell adenylate cyclase, whereas the B subunit binds to the GM_1 ganglioside of intestinal enterocytes.[121,126,166,237] The instability of enterotoxin at $pH < 6.0$ points to its limited role in *Salmonella* pathogenicity during the inclusion of the pathogen in phagolysosomes and acidified epithelial vacuoles. *Salmonella* spp. also produce a thermolabile cytotoxin associated with the outer membrane.[47,439,554] The trypsin- and protease-sensitive cytotoxin is stable between pH 7.0 and 8.0 but is inactivated rapidly outside this pH range.[200,439] The cytotoxin is not related serologically or genetically to Shiga-like toxins as evidenced by the inability of Shiga and *E. coli* Vero 1 and 2 antitoxins to neutralize *Salmonella* cytotoxin, and by the failure of Shiga toxin-specific probes to hybridize with total *Salmonella* DNA.[47,200] Maximal production of cytotoxin occurs in the early stationary phase of growth at pH 7.0 and diminishes as the incubation temperature increases from 35° C to 42° C or as the pH shifts from neutrality.[200] Although the cytotoxic action mechanism is poorly understood, inhibition of protein synthesis in host cells[390] and membrane disruption through a cytotoxin-dependent chelation of Ca^{+2} and Mg^{+2} associated with host cell membranes have been reported.[508] Clearly, these lytic events enhance strain virulence by facilitating the dissemination of salmonellae within host tissues. A similar function has been ascribed to a 50 kDa Zot-like protein encoded on a 5.5 kbp genomic DNA segment that maps between 10 and 20 min on the chromosome and occurs infrequently in *Salmonella* strains.[660] The toxin disrupts the intercellular tight junction of enterocytes, thereby facilitating the migration of salmonellae from an infected enterocyte into a neighboring host cell. Synergism between the destructive effect of cytotoxin and Zot proteins on host cells, the endotoxin-induced inflammatory response, and the enterotoxin-dependent efflux of water and electrolyte in enterocytes all contribute to the clinical presentation of human salmonellosis. Finally, a poorly characterized hemolytic salmolysin is also associated with *Salmonella* spp. This thermolabile 16.7 kDa protein is encoded by the *sly A* locus. The observation that the median lethal dose of a *sly A* mutant of *S.* Typhimurium in mice was markedly greater than that for the wild-type parent indicates a role of salmolysin as a virulence determinant.[417]

45.5 INCIDENCE OF THE ORGANISM IN THE ENVIRONMENT AND IN FOODS

45.5.1 Agriculture and Aquaculture

The ubiquity of *Salmonella* spp. in the natural environment contributes significantly to the continued prominence of salmonellae in meat animals and derived products (Table 45–5). The on-farm infection of cattle follows from a liberal access to surface waters contaminated with industrial and farm effluents or from infected wildlife. The potentially high organic content of surface waters together with climatic conditions that favor the growth of bacteria could expose farm animals to massive doses of salmonellae. Spread of *Salmonella* also could stem from the repeated contact of animals with carriers within the herd or from the consumption of contaminated commercial feeds. Feeding of untreated animal wastes to livestock also contributes to herd infection.[298] Intensive husbandry in the porcine and poultry industries as well as animal behavior creates difficulties in maintaining adequate hygienic conditions in rearing pens, and in limiting cross-contamination between animals. The introduction of infected poultry replacement stocks in sanitized premises, unrestricted access of birds to fecally contaminated communal drinking stations, provision of *Salmonella*-contaminated poultry feed, and the high density of birds in rearing facilities synergistically

Next Page

contribute to the continued prominence of salmonellae in poultry operations. Animal feeds likely are a major reservoir of *Salmonella* spp. (Table 45–6). Although the large-scale thermal processing of animal offals targets the destruction of pathogenic bacteria, the operation of cookers at suboptimal conditions, contamination of rendered feeds with raw product, and the bulk storage and shipment of rendered animal proteins can undermine the quality and safety of finished products.[71] Raw materials of vegetal origin also can introduce salmonellae in finished feed products (Table 45–6).[20,671] Although the numbers of *Salmonella* in feed and feed ingredients tend to be low, values of 10^3 salmonellae $(100\ g)^{-1}$ of product have been reported.[71,75,169,180] The efficacy of pelleting in markedly reducing the bacterial load in feed mash relies on the processing of materials at ≥ 80° C and an adjusted 15% moisture content.[319,450,671] The value of propionic, formic, lactic, fumaric, and citric acids in the postprocess decontamination of feeds has been examined.[73,320] The efficacy of commercial mixtures of propionic and formic acids (BioAdd™, Sal Curb™) in reducing the vertical transmission of *Salmonella* in animal husbandry has yet to be confirmed. There is evidence, however, that these feed additives may also exert an antibacterial effect in the crops of birds, thereby affording protection against other environmental sources of infection.[320,346]

Slaughtering-plant operations generally amplify the level of bacterial contamination associated with live animals. The stress-induced shedding of *Salmonella* during transportation from the farm to the slaughterhouse and the containment of animals in holding pens before slaughter markedly increase the propensity for cross-contamination.[93,468,469,477,706] The hygienic removal of fecally soiled animal hides and the risk of cross-contamination of carcasses during the cutting, trimming, and rinsing of animal tissues pose a major challenge to the meat industry.[93,272,469,612] The situation is particularly difficult in poultry slaughterhouses that receive stressed birds with fecally contaminated body surfaces. After electrical stunning and bleeding, birds are hung on mechanical lines and briefly passaged through a common immersion scald tank operated at 50° C to 60° C.[490,611] Scalded birds are then defeathered by the shearing force of a rotary drum picker that spreads bacterial surface contamination between carcasses.[133,703] Scalding, defeathering, and evisceration are critical control points in the hygienic processing of poultry. The wide variations in the reported national prevalence of salmonellae in preslaughter and postslaughter animals (Table 45–5) likely reflect differences in the endemicity of the microorganism in individual countries, the nature of test materials, the stringency of sampling, and the analytical method used to detect the organism. The reported national incidence of salmonellae in retail meats varies widely (Table 45–7). Inadequate refrigeration and hygienic control during slaughtering and distribution, and the mishandling of meat products in local butcher shops, undoubtedly contribute to the generally higher level of contamination in meat products from developing countries. The high prevalence of *Salmonella* in retail poultry reflects the continued inability of the industry to effectively prevent the spread of this microorganism during the production, slaughtering, and marketing of raw poultry meat (Table 45–8).

Horizontal spread of salmonellae among layer hens and vertical transmission of the bacteria on the shell egg surface and within the egg are problems for the egg industry (Table 45–9). Although the aqueous sanitizing of shell eggs at 41° C and pH ≥10.0 reduces external surface contamination, the practice disrupts the structural integrity of the outer protective cuticle and facilitates penetration of salmonellae through exposed pores in the egg shell.[329,449,477] Concerns on the safety of intact shell eggs have increased dramatically in recent years because of the possible transovarian transmission of *S.* Enteritidis into the egg magma prior to shell deposition.[144,561] The transovarian infection of eggs also has been associated with other serovars including *S.* Thompson, *S.* Menston, *S.* Typhimurium, *S.* Pullorum, and *S.* Gallinarum.[60,282] Internally contaminated shell eggs pose a significant public health risk unless the eggs are boiled for more than 8 min or cooked until the yolk is well congealed.[343] The prevalence of internally contaminated shell eggs generally is very low (Table 45–9).

Salmonellae are often present in ethnic raw meats (Table 45–10) and in raw fish and shellfish (Table 45–11). Although marine waters generally are considered to be free of *Salmonella* spp., estuaries and coastal waters contaminated with human and agricultural wastes pose a human health hazard (Table 45–11). The use of rinse water and packaging ice from contaminated sources, poor personal hygiene among nonspecialized workers, and repeated manual handling of raw products during the harvesting and packaging operations may have contributed to the higher rates of contamination in fish and shellfish from Asia. The rapid depletion of feral stocks of marine and freshwater species coincident with a growing consumer demand for these products favored an acceler-

ated expansion of the aquacultural industry. Asia is responsible for more than half of the world's aquacultural output.[164] Isolated studies on the *Salmonella* status of aquacultural fish and shellfish demonstrate their potential as vehicles of human salmonellosis (Table 45–11). The popularity of raw fish dishes (sushi) in Asia, North America, and Europe together with the abundance of culinary recipes involving lightly cooked fish and shellfish expose consumers to potentially serious health problems.

Raw milk is the principal reservoir of *Salmonella* spp. in the dairy industry (Table 45–12). Contamina-

tion arises mainly from inadequately sanitized milking equipment and poor disinfection of teat skin prior to milking. Intramammary *Salmonella* infection associated with subclinical mastitis also could lead to the intermittent shedding of salmonellae in raw milk. Temperature fluctuations from the periodic addition of fresh warm milk into on-farm refrigerated storage tanks encourage the growth of salmonellae and undermine the safety of cheese manufactured from raw or thermized (unpasteurized) milk. Prolonged refrigerated storage of raw milk on dairy farms or in industrial silos also would favor the proliferation of psychrotrophic *Salmonella*.[162,363] Following inoculation into fresh milk that had been autoclaved at 100° C for 17 to 20 minutes, growth of *S.* Typhimurium and *S.* Dublin was not detected during storage at 6° C for 6 months. However, pooled strains of *S.* Typhimurium grew slowly at 8° C and 12° C with lag periods of 600 and 8.8 hours and generation times of 83.5 and 8.45 hours respectively.[379] The persistence or growth of *Salmonella* spp. in raw milk and in nonpasteurized dairy products has led to several important outbreaks of human salmonellosis (Section 45.6).

Several factors can contribute to the *Salmonella* contamination of fresh fruits and vegetables (Table 45–13). These include spray or canal irrigation of growing fields with contaminated water, fertilization of farmlands with untreated animal wastes, contamination of crops by infected wildlife, rinsing or cooling of harvested products with *Salmonella*-contaminated water, and multiple manual handling of fruits and vegetables during harvesting, processing, and packaging.[61,335,345] *Salmonella* can multiply on the surfaces of fruits such as tomatoes[685,716] and cut melons[226,280] and on fresh vegetables manually or mechanically moisturized during their retail display at ambient temperature.[96] Clearly, fresh produce to

be consumed raw should always be rinsed thoroughly with potable water. Recent reports on the occurrence of salmonellae in ready-to-eat sesame seed products such as tahineh and halawa have raised new concerns on the safety of these widely distributed ethnic foods (Table 45–13). Both products are derived from roasted sesame seeds dehulled and milled to an oily paste. Tahineh is widely used in regions of the Middle East as a base ingredient for seasoned sauces and for hummus, a blended mixture of tahineh and chickpeas. Halawa is a thickened and sweetened tahineh-based dessert. Although the products are generally stored unrefrigerated in wholesale and retail outlets, the low water activity (a_w) of tahineh and halawa inhibits the growth of salmonellae but does not affect their survival in products stored for up to 4 months at ambient and refrigerator temperatures (D'Aoust, unpublished data). Contaminated tahineh and halawa imported into Canada originated from several manufacturers in Lebanon (Table 45–13). Subsequent monitoring of both sesame seed products in Canada and the US identified contaminated lots imported from several Middle Eastern countries. In considering the absence of published reports linking human salmonellosis with the consumption of these products, it should be recognized that for reasons discussed in Chapter 37, epidemiological investigations of outbreaks and sporadic cases do not always identify the causative food source.

45.5.2 Antibiotic Resistance

In addition to earlier considerations on the development of bacterial resistance and the widespread use of antimicrobial drugs in human medicine (Tables 45–3 and 45–4), the massive veterinary use and abuse of medically important antibiotics has

contributed to the emergence and persistence of resistant salmonellae in the global food chain.[166,349,703] This deplorable situation stems from the lack of veterinary control on the use of antimicrobials in the treatment of diseased animals and, more importantly, in the widespread administration of subtherapeutic doses of antibiotics in feeds for growth promotion and for prophylaxis in meat animal husbandry. The international prevalence of antibiotic-resistant salmonellae in the poultry, porcine, and bovine meat industries is disquieting (Table 45–14). It is generally recognized that the widespread occurrence of streptomycin, tetracycline, and sulfa drug resistance in meat isolates results from the frequent agricultural use of these antibacterial agents at subtherapeutic levels.[176,349,703] The problem is amplified by the inability of slaughtering plants to significantly reduce the numbers of bacterial pathogens on meat carcasses and to effectively prevent cross-contamination within the plant environment.[703] The high levels of ampicillin resistance (≥80%) in meatborne *Salmonella* isolates from Brazil, France, and the US and the prominence of chloramphenicol and trimethoprim sulfamethoxazole-resistant salmonellae in raw meats from numerous countries are of great concern (Table 45–14). It has been reported that 20 (45%) of the 44 million pounds of antibiotics manufactured in the US in 1986 were used in the meat animal industry and that an estimated 90% of these antimicrobials were administered at subtherapeutic levels.[349] The use of prophylactic and growth-promoting antibiotic regimens and their role in the selection of resistant salmonellae in raw meat products is under review by the World Health Organization (Berlin 1997) and other national agencies.[330,493,619] The aquacultural industry is equally vulnerable to the emergence and persistence of antibiotic-resistant strains because it commonly uses antibiotic prophylaxis to safeguard the vigor of reared fish and shellfish.[176] The aqueous environment and the warm climates generally associated with aquacultural farms together with sedimentation of animal wastes and medicated feeds allow bacterial proliferation in earthen ponds and basins and the cross-contamination of reared species with resistant *Salmonella* strains.

The problem of antibiotic resistance is compounded by a natural propensity for the genetic transmission of resistance determinants via R-plasmids.[162,166] The conjugative intrageneric and intergeneric transfer of R-plasmids between compatible cells likely contributes to the high incidence of multiple antibiotic–resistant *Salmonella* strains in agricultural sectors (Table 45–14).[55,586] Antibiotic-resistance and virulence determinants can occur on a common plasmid and thus heighten public health concerns.[580,583,649] Several growth-promoting or prophylactic antibiotics such as apramycin, virgin-

iamycin, tylosin, and avoparcin are widely used in animal husbandry and are regarded as veterinary drugs because of their limited therapeutic value in human medicine. However, the on-farm use of apramycin and avoparcin selects for meatborne bacteria resistant to the related and medically important gentamicin and vancomycin.[519,645,667] The bivalent resistance of *S.* Typhimurium to apramycin and

gentamicin is encoded on separate plasmids and stems from an acetyltransferase type IV–dependent inactivation of both aminoglycosides.[444,650]

Synthetic fluoroquinolones have been used increasingly in recent years for the treatment of systemic bacterial infections. Their efficacy derives from the inactivation of the active (A) site of the bacterial gyrase enzyme responsible for the stability and supercoiling of chromosomal DNA.[104] Bacterial resistance to fluoroquinolones may arise from a porin-dependent change in cell permeability or a mutation in the genomic *gyr A* locus encoding the gyrase subunit A protein[166,288,555] or as a result of gene-encoded alterations in the gyrase subunit B (binding) protein.[264,309] The therapeutic efficacy of the novel fluoroquinolones in human medicine is progressively being undermined by their increased prophylactic and therapeutic use in agriculture and aquaculture.[163,166] Fluoroquinolones originally were introduced to gap the therapeutic void created by the increase in bacterial resistance to other antibiotics (Tables 45–3 and 45–4). Since 1987, there has been a disquieting trend in government approval of the fluoroquinolones enrofloxacin in European countries[221,247,289,311] and sarafloxacin in the US[23] for the treatment of poultry and porcine infections. Complacency in promulgating proscriptive regulations on the use of fluoroquinolones in the food industry could bear devastating consequences on the safety of the global food supply and on the health of consumers. The incidence of bacterial cross-resistance to fluoroquinolones in veterinary isolates heightens public health concerns.[355,586] There are reports of 8.5% to 18.8% nalidixic acid resistance in *Salmonella* isolated from poultry and poultry feeds from Brazil,[74] France,[579] and The Netherlands,[355] of 3.2% to 12.9% enrofloxacin resistance in beef and chicken isolates of *S.* Typhimurium and *S.* Enteritidis in Germany,[658] and an increasing enrofloxacin resistance from 1.8% to 15.9% between 1988 and 1990 in bovine isolates in Germany.[311]

45.6 EPIDEMIOLOGY

Salmonella spp. are a leading cause of bacterial foodborne disease in most countries except Japan where *Vibrio* spp. dominate because of consumer preference for raw or lightly cooked fish and shellfish products (Table 45–15). The numerical data for a given pathogen are not directly comparable between countries because of national inequities in the reporting of diarrheal diseases and in the complete identification of infectious agents.[653,705] The data are nonetheless indicators of the true incidence of foodborne salmonellosis within individual countries. The ongoing pandemic of human *S.* Enteritidis infections has probably contributed significantly to the high numbers of foodborne *Salmonella* incidents in England and Wales, France, Italy, Spain, and Poland (Table 45–15). Dramatic increases in human foodborne salmonellosis (Figure 45–1) have been reported in recent years in France,[413,428,446,514] Austria,[705] Italy,[705] and England and Wales,[18,28,616] whereas the reported incidence continues to fluctuate in Scotland,[482] Spain,[207] Canada,[241,242] Israel,[705] and the US.[63]

Poultry, eggs, and egg products commonly were implicated in human *Salmonella* infections (Table 45–16). In spite of warnings from government and consumer protection agencies that the consumption of undercooked poultry and shell eggs and the addition of raw eggs to nonthermally processed foods are potentially hazardous, food preparators in food service establishments and private homes too often ignore this advice.[389,591,705] The growing popularity of raw meat dishes such as steak tartare, sushi, and the traditional light cooking of fish and shellfish indicate that consumer education on foodborne health risks remains a formidable challenge.[564,705] Although raw pork generally is well cooked to eliminate the threat of *Trichinella* parasites, neglect in the proper handling and cooking of this product can lead to human salmonellosis (Table 45–16). The use of raw or undercooked eggs in bakery products frequently is associated with *Salmonella* infections.[461,652] Raw milk remains an important vehicle of human *Salmonella* and other bacterial infections.[58,159,251,603] The health risks from the unrestricted retail sale of raw fluid milk in Scotland, Northern Ireland, England, and Wales were alleviated by proscriptive regulations in 1983–1985.[58] The retail sale of certified raw milk on the western coast of the US has also been associated with several episodes of human salmonellosis.[16,124,239] *Salmonella* outbreaks from pasteurized fluid milk were attributed to human error during milk processing or to postprocess contamination.[105,159,219,599] Properly controlled pasteurization eliminates vegetative bacterial pathogens from raw milk.[179,181,231] The debate concerning the enhanced flavor and nutritive value of raw milk cheese and the inherent bacterial health risk remains highly controversial. Major disease outbreaks from the consumption of raw milk cheese (Table 45–17) and the limited pathogen reductions during the mandatory 60-day refrigerated storage of cheese manufactured from unpasteurized milk clearly support the exclusive use of pasteurized milk in cheese produc-

[b] Not listed or possibly no reported outbreaks.

[c] A total 247 incidents of *Vibrio* spp. enteritis was reported.

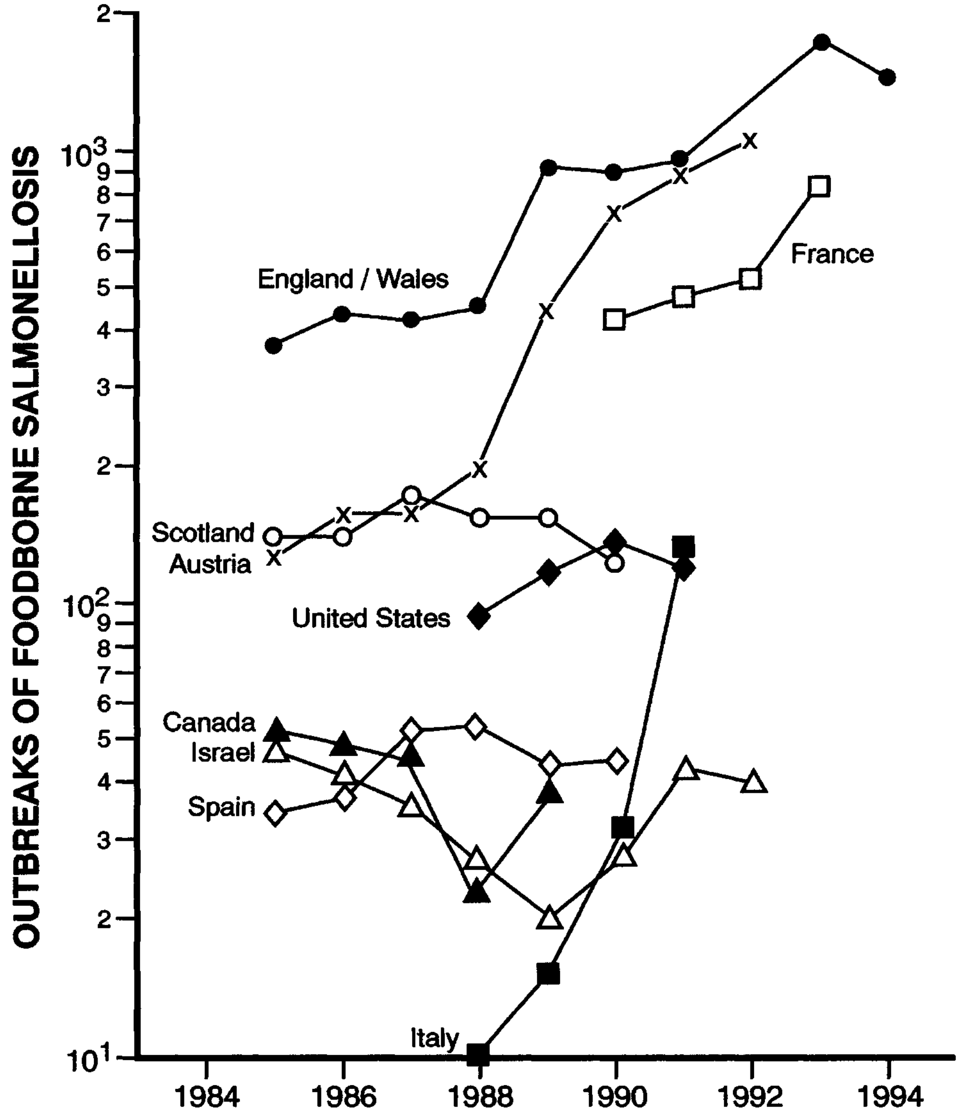

Figure 45–1. Trends in Reported Foodborne Salmonellosis

tion.[159,173,688,700] Fresh fruits and vegetables have gained notoriety in recent years as vehicles of human salmonellosis. The use of fresh or inadequately composted animal wastes as fertilizer, contaminated waters, and effluents for field irrigation, and nonpotable water for postharvest washing and production of ice for cold shipment of perishable products likely contributed to recent outbreaks attributed to fresh produce (Table 45–18). Alfalfa and mung bean seeds imported from Australia and The Netherlands were identified as the source of most sproutborne outbreaks.[437,536] Salmonellae may survive antibacterial treatments applied to seeds and can proliferate during seed germination.[82,356] The storage of freshly cut fruits at room temperature would favor the growth of salmonellae transferred from the rind of melons[164,280] or the surface of tomatoes[422,685,716] to edible tissues during slicing.

Dairy products figured prominently in the last decade as vehicles of major outbreaks of human salmonellosis (Table 45–19). Cheddar cheese made from pasteurized and thermized (unpasteurized) milk was adulterated following the manual override of a flow diversion valve, thereby channelling raw milk into vats of heat-treated cheese milk.[173] A single asymptomatic cow shedding the outbreak strain of *S.* Typhimurium PT10 from her right hind teat tentatively was identified as the source of contaminated

milk.[489] A massive outbreak of *S.* Typhimurium infection from pasteurized fluid milk resulted from a cross-connection between raw and pasteurized milk lines.[408] This episode remains the worst food poisoning incident in the US. The report of human *S.* Paratyphi B infections from unpasteurized goat milk cheese reiterates the inherent health hazard of raw milk.[198] Contamination of pasteurized ice cream mix during transport in trucks that previously had hauled raw liquid eggs led to a multistate outbreak of *S.* Enteritidis in the US.[314,315] A chilled beverage prepared with raw liquid eggs and served in a popular cafe that used unsanitary kitchen practices was incriminated in a large outbreak in the Republic of China.[709] Norwegian chocolate adulterated with *S.* Typhimurium led to disease outbreaks in Norway and Finland; the source of product contamination could not be ascertained.[377] A commercially distributed cooked egg dish ("nishikiito tamago") and spiced Italian-style prosciottino ham purchased from delicatessens and restaurants caused major outbreaks of salmonellosis in Japan and the US, respectively.[19,463] Fresh cantaloupes produced in the southern US were linked epidemiologically to nationwide outbreaks of *S.* Poona in Canada and the US.[245] A contaminated mixture of flaked tuna and raw egg mayonnaise prepared in a central kitchen and served in school cafeterias led to an outbreak of *S.* Enteritidis that affected 751 individuals, many requiring hospitalization.[556] Contaminated paprika sprinkled onto nationally distributed potato chips was implicated in a major episode of human salmonellosis in Germany.[412] In addition to the three principal serovars isolated from patients, paprika imported from South America, and paprika potato chips (Table 45–19), a total of 94 salmonellae including newly identified serovars and unusual strains capable of growth in KCN were recovered during the outbreak period. A disease outbreak of *S.* Bovismorbificans in Finland and Sweden was attributed to alfalfa seeds imported from Australia and germinated in different sprouting facilities in both Scandinavian countries.[521] The increasing movement of food in international trade, the national disparities in quality control programs and safety standards, and overextension of inspection and analytical capabilities in importing countries likely contributed to international outbreaks of foodborne salmonellosis (Table 45–20).

45.7 FACTORS AFFECTING GROWTH AND SURVIVAL IN FOODS

45.7.1 Growth

Mesophilic *Salmonella* have been reported to grow in the temperature range of 2° C to 47° C and up to 54° C for a thermally stressed mutant of *S.*

Typhimurium.[160,162,166,211,212] The ability of salmonellae to proliferate in chill-stored foods emphasizes the importance of adequate refrigeration and rapid turnover of perishable foods. The latter increasingly are being packaged under vacuum or modified atmospheres consisting of 60% to 80% CO_2 with varying proportions of N_2 and/or O_2 to prolong shelf-life through the inhibition of aerobic spoilage microorganisms.[128,162] In fact, modified atmosphere packaging (MAP) removes these natural organoleptic indicators of temperature abuse of the product. Populations of *Salmonella* can remain unchanged at high concentrations of CO_2 but rapidly multiply in foods packaged under 20% to 50% CO_2.[77,348] Preconditioning at low temperatures can increase the growth rate of *Salmonella* at low temperatures and the minimum temperature for growth may be lower in foods than in laboratory media.[6,160,162] The minimum temperature for growth prevails at neutral pH and increases sharply as pH deviates from neutrality.[448] Salt concentrations of ≥ 2% (w/v) reportedly delay the growth of salmonellae.[454] The proliferation of salmonellae at $a_w \geq 0.93$ varies between strains and depends on the composition of the food.[160] Refrigerator temperatures amplify NaCl-dependent bacteriostasis whereas increasing temperatures increase bacterial salt tolerance.[9,643] For example, the maximum NaCl concentration for the growth of S. Typhimurium in brain heart infusion broth (pH 6.8) at 10° C and 15° C was 2% and 6%, respectively.[269] Salt-dependent reductions in growth rate may result from altered enzyme configurations and reaction kinetics or from the expenditure of cellular energy to maintain ionic homeostasis. *Salmonella* spp. grow at moderate temperatures (25° C to 43° C) in the pH range of 3.6 to 9.5 with an optimum pH of 6.5 to 7.5.[49,127,329,572] The minimum pH for growth was determined in a defined broth medium acidified with HCl.[572] The antibacterial action of acetic and propionic acids exceeds that of the naturally occurring citric acid or that of lactic acid produced during the fermentation of meat and dairy products.[127,160,454,572] Slow acidification during fermentative processes likely encourages pH adaptation and growth of salmonellae under normally inhibitory acidic conditions.[337] Acid tolerance at pH ≤ 5.0 increases with increasing temperature.[9,238,643] A growth study of *Salmonella* on NaCl-pH gradient plates varying from 2.7% to 10% NaCl and pH 3.76 to 7.9 confirmed the primacy of pH as growth determinant.[643] Interestingly, supplementation of complex and defined broth media with 2% (w/v) NaCl or KCl and adjustment to pH 5.2 with acetic acid showed low salt-dependent growth stimulation of S. Enteritidis at 25° C and 37° C.[538] The protection afforded by low salinity may be linked to the Na^+/K^+-proton antiport system and maintenance of cellular homeostasis.[166] Predictive (stochastic) modelling allows food manu-

facturers to estimate the shelf-life and safety of products. The models are mathematical derivations that delineate the probable growth or survival response of foodborne bacteria under different combinations of pH, temperature, salt concentration, a_w, or other environmental factor of interest (Chapter 16[270,318,567]). The predictive power of this approach stems from the development of a large database on bacterial responses in broth media or food matrices under defined and controlled test parameters. These responses are then fitted to mathematical equations which, by interpolation, putatively predict the behavior of salmonellae or other bacterial species under particular environmental conditions. Predictive models are not without limitations.[270,567] Their application to conditions outside the boundaries of the experimental database could lead to erroneous conclusions. The physiological heterogeneity within the *Salmonella* genus undermines the reliability of models based on data from a few serovars. The types and numbers of endogenous microflora in foods could also affect the growth and survival of salmonellae but this variable has yet to be adequately factored into predictive models. The different behavior of microorganisms in liquid and on solid media also dictates caution in the use of predictive models derived from bacterial responses in aqueous environments.[101,102] The field of predictive modelling is rapidly expanding and striving to address the fate of bacterial pathogens in complex food systems,[213,689] under fluctuating environmental conditions,[565] and in different physiological states.[318] Predictive models are commercially available in the UK and the US in the form of the Food Micromodel and the Pathogen Modeling Programs, respectively.

45.7.2 Survival

The potential survival of *Salmonella* under extreme environmental conditions is a major public health concern. The fate of salmonellae during freezer storage is strain- and food-dependent, where the number of viable cells gradually decreases during storage at –20° C or lower with more rapid death at near-freezing temperatures.[57,160,166] *Salmonella* have survived in ice cream and raw snails stored for many years at –20° C or lower.[160] Survival also hinges on the physiological state of the microorganism prior to freezing.[80] Short (30 min) adaptation of *S.* Enteritidis to low temperatures (5° C to 10° C) prior to rapid freezing at –78° C greatly enhanced survival. Cold temperature adaptation induced the synthesis of a genomic *csp* A-encoded cold shock protein whose specific role in freezer protection remains undetermined.[358] Although the low a_w in dry foods inhibits the growth of salmonellae, it also triggers bacterial stress responses that promote greater survival and potentiate outbreaks of human salmonellosis, (Tables 45–19 and 45–20).[160] Survival in dry products is dependent on a_w, temperature, and food type. An increase in the moisture content of dry products including milk powder, cocoa powder, and animal feeds stored at room temperature or storage of dry foods at an elevated temperature (>25° C) enhances bacterial lethality.[56,373]

Salmonella can survive in low pH environments such as naturally acidic, acidified, and fermented foods.[160,415,502,659] This is of particular concern because, in some circumstances, the infectious dose for humans can be low.[164] Several strains of salmonellae were inactivated within hours in sweet pickle relish (pH 2.8) and mustard (pH 3.1) but survived 24 hours in ketchup adjusted to pH 3.6.[659] Similarly, acid-conditioned (pH 5.0) *Salmonella* inocula survived for 27 and 73 days in orange juice adjusted with citric acid to pH 3.5 and 4.0, respectively.[502] A mixture of *Salmonella* in a commercial reduced-calorie mayonnaise was rapidly inactivated as the pH was adjusted from 4.3 to 3.9 with acetic acid.[277] Acidification of mayonnaise with acetic acid was markedly more effective than citric acid at pH values of 4.8 to 5.2 in reducing levels of *S.* Muenster during storage at 25° C.[137] Studies on the decontamination of meat carcasses have also confirmed the greater lethality of acetic acid.[202] In contrast to cold temperatures, which promote bacterial survival in mayonnaise, holding this food at room or higher temperatures more effectively inactivates *Salmonella* spp.[426,481,507,659] The identity of vegetable oil used in the preparation of mayonnaise also influences survival of *Salmonella*.[539]

A constitutive pH homeostasis system maintains the cytoplasm of *Salmonella* cells at pH ≥ 6.0 under mild to moderate environmental acid conditions (pH > 4.0). Control mechanisms include the low permeability of the cytoplasmic membrane to protons, a proton translocating ATPase that pumps cytoplasmic H^+ into the cell exterior, the H^+ and Na^+/K^+ antiport system that exchanges cytoplasmic H^+ with monovalent cations from the external medium, and the electron transport chain that converts protons into water. Acid-induced bacterial decarboxylases also contribute to pH homeostasis by generating amines that neutralize H^+ in the cytoplasm.[244,317,491] These mechanisms fail under extreme acidic conditions, resulting in bacterial cell death.

The physiological state of salmonellae as affected by growth conditions has an impact on acid resistance. Growth of *S.* Enteritidis at 37° C to 44° C induced greater acid resistance (pH 2.6) than growth at 20° C. A sudden temperature shift from 20° C to 37° C–46° C triggered a similar bacterial response.[342] Acid resistance can also be enhanced if salmonellae first are adapted to moderately acid conditions (pH > 4.3) prior to their exposure to otherwise bactericidal conditions (pH 3.0 to 3.3). The phenomenon termed acid tolerance response (ATR) hinges on the synthesis of acid shock proteins.[243] Different ATR systems are activated in the logarithmic and stationary phases of growth. Pre–acid-shock adaptation (pH 5.8) and acid shock adaptation (pH 4.3) both have been used to induce ATR in log phase cells. In the pre–acid-shock adaptation, salmonellae are maintained in minimal glucose broth medium at pH 5.8 for one-cell doubling prior to acid challenge at pH 3.0 to 3.3. The acquired resistance results from an induced elevation in cytoplasmic pH that permits *Salmonella* spp. to synthesize protective acid shock proteins under normally inhibitory acid (pH 3.0 to 3.3) conditions. The alternate sigma factor (σ^s) encoded by the *rpo S* locus is an essential element in this protective response. Acid shock adaptation in cells held for ≤ 60 minutes at pH 4.3 can lead to either transient or sustained responses in log phase salmonellae. Although the induction of the transient ATR is independent of the alternative sigma factor (σ^s), the response is modulated by the gene product of the *fur* iron regulator locus, which controls the expression of several acid shock proteins.[243] In contrast, the sustained ATR is σ^s-dependent and more rigorously protects log phase cells against the acid environments. The acid shock (pH 4.3) also induces a rapid four- to five-fold increase in cellular levels of σ^s that specifically directs the synthesis of 8 of the 51 acid-shock proteins associated with the ATR in log phase salmonellae. High levels of σ^s alone do not confer resistance unless cells also are subjected to an acid shock. Although the underlying protective mechanisms have yet to be fully elucidated, the ability of salmonellae to efficiently repair acid-damaged DNA plays a determinant role in bacterial survival. Two ATRs associated with salmonellae in the stationary phase of growth engender the synthesis of up to 15 acid shock proteins.[243] A general stress response is induced when salmonellae enter the stationary phase of growth. This σ^s-dependent system is not acid inducible. In contrast, a second stationary-phase ATR is acid inducible but σ^s-independent. The protective capacity of these responses greatly exceeds that afforded in log phase ATRs. Current evidence suggests that the acidity of the extracellular and cytoplasmic environments induces the synthesis of different sets of protective acid shock proteins. Induced acid tolerance also engenders resistance to thermal, osmotic, and oxidative stress conditions.[243,416] Conversely, heat stress affords cross-protection against normally lethal acidic microenvironments.[342]

Salmonella poorly withstand exposure to pH >10.0, which disrupts the cytoplasmic membrane.[118,329,388,456] Synergism between high alkaline pH and elevated temperatures increases the death rate.[497,639]

The acquired or induced thermoresistance of *Salmonella* underlines the importance of commercial heat processes in providing safe and wholesome foods. The greater heat tolerance of salmonellae in the stationary than logarithmic phase of growth and in cells preconditioned at sublethal temperatures (≤50° C) or grown in nutritionally rich media derives, in part, from the synthesis of heat shock proteins and/or alteration of cytoplasmic membrane fluidity.[108,118,166,342,636] A few highly heat-resistant strains such as *S.* Senftenberg 775W[391,401,480] and *S.* Irumu[81] have been reported. Heat resistance frequently is expressed in terms of decimal reduction time (*D*), which represents the amount of time required at a stated temperature to effect a 1.0 $\log_{10}$ reduction in the number of viable microorganisms. The heat resistance of *Salmonella* varies inversely with the a_w of the heating menstruum,[160,628] and is also modulated by the nature of low molecular weight solutes therein.[140,160,391,496] For example, sucrose adjusted to a_w = 0.90 confers greater heat resistance to *S.* Typhimurium at 57.2° C than glycerol at the same a_w value.[279] Although the mechanism for a_w- and solute-dependent increase in heat resistance remains uncertain, induced plasmolysis could trigger structural alteration of enzymes to heat-resistant configurations.[160] Heat resistance tends to be highest at pH values approaching neutrality.[497] Thermal inactivation models were recently developed for *S.* Enteritidis using temperature (54.5° C to 64.5° C), pH (4.2 to 9.6), and NaCl (0.5% to 8.5%) as controlling factors.[86]

Standard procedures for the pasteurization of egg yolk products in the US include heating of liquid egg yolk for 3.5 minutes at 61.1° C, egg yolk with 10% NaCl, 10% sucrose, or 10% NaCl plus 5% sucrose for 3.5 minutes at 63.3° C, and egg yolk with 20% NaCl for 3.5 minutes at 64.4° C.[496] The *D* (61.1° C) values for mixtures of *S.* Enteritidis and *S.* Typhimurium inoculated into plain yolk ranged from 0.16 to 0.57 minutes, which correspond to 6.14 to 21.9 $\log_{10}$ reductions in a standard 3.5-minute pasteurization process.[496,590] The heat resistance of test strains increased in the presence of a_w-reducing solutes. For example, the *D* (63.3° C) value of a mixture of *Salmonella* strains increased from 0.20 minutes in liquid egg yolk to 0.72 and 11.50 minutes in egg yolk supplemented with 10% sucrose and 10% NaCl, respectively.[496] The modest 0.3 $\log_{10}$ reduction obtained with the standard 3.5 minutes processing of salted products at 63.3° C indicates that this thermal process would not confer product safety for raw egg yolks containing 10% NaCl and high incident levels of salmonellae. Temperature upshifts also can increase bacterial heat resistance. The *D* (56° C) value of *S.* Enteritidis phage-type 4 grown at 20° C was 0.91 minutes, and 14.4 minutes for bacteria grown at 44° C.[342] The use of wash-water tanks held at 32° C to 46° C to sanitize eggshell surfaces and the subsequent slow cooling of washed shell eggs may induce heat-shock protein synthesis and enhance bacterial heat resistance.[368,430]

Commercial thermal processing of raw eggs plays a key role in the bacteriological safety of derived products particularly in relation to *S.* Enteritidis (see Section 45.5.1). Although an early report suggested that *S.* Enteritidis phage-type 4 was highly thermotolerant,[341] subsequent evidence suggests that this and other phage-types of *S.* Enteritidis are not unduly heat-resistant.[496,590,596] The pasteurization of liquid egg white presents a major challenge because its desirable functional properties are destroyed rapidly at elevated temperatures.[497] The transovarian transmission of *S.* Enteritidis into shell eggs and the frequent localization of this pathogen in egg albumen emphasize the importance of effective liquid egg pasteurization.[341,344] Parameters for the pasteurization of liquid egg white were developed when the pH of the raw products ranged from 8.9 to 9.1. The currently more efficient movement of shell eggs from commercial layer farms to egg-breaking stations now provides egg albumen with a pH close to 8.2.[497] The resulting reduction in the pH of whole egg melange[15] or liquid egg white[260,497,590] dramatically increases the heat resistance of *Salmonella* spp. These concerns led to a reassessment of the lethality of conventional heating regimens for liquid albumen which include 3.5 minutes at 51.7° C in the presence of H_2O_2, 6.2 minutes at 55.6° C, and 3.5 minutes at 56.7° C.[662] Using a submerged vial technique and mixtures of *S.* Enteritidis, *S.* Typhimurium, and *S.* Senftenberg, none of the foregoing heat processes achieved the minimum 4.0-log reduction in viable salmonellae.[497] Similarly, pooled strains of *S.* Enteritidis and *S.* Typhimurium inoculated into albumen (pH 8.2) and heated in sealed glass vials yielded a *D* (56.7° C) value of 2.96 minutes which corresponds to a 1.18 $\log_{10}$ reduction in a standard 3.5 minutes pasteurization process.[590] Lower heat resistance was observed in albumen (pH 9.1) with *D* (56.7° C) value of 1.58 minutes.

Pasteurization of raw milk at 71.7° C for 0.25 minutes or under equivalent time-temperature regimens targets a 5.0 $\log_{10}$ or greater reduction in the number of viable salmonellae.[663] *D* values of 0.11 minutes (62.8° C) and 0.004 minutes (71.7° C) were obtained for the *S.* Typhimurium strain associated with the largest milkborne outbreak (1985) in the US. It was suggested that the outbreak resulted from postprocess contamination of milk rather than deficiencies in the proper operation of the pasteurizer.[97] Thermization is widely used in the cheese industry and involves the holding of raw milk for short (nonpasteurizing) periods of time at temperatures ranging from 60° C to 69° C. In a pilot plant study on the fate of *Salmonella* spp. in thermized cheesemilk,[179] the *D* values for 10-strain mixtures of salmonellae inoculated into raw milk and heated for 0.27 to 0.29 minutes at 60° C in a high temperature, short time (HTST) pasteurizer ranged from 0.058 to 0.098 minutes, which correspond to a 3.0 to 5.0 $\log_{10}$ reduction in viable salmonellae. Thermal processing of these strains at 63° C or greater generally produced more than 6.0 $\log_{10}$ reductions. In contrast, the heat-resistant *S.* Senftenberg 775W required treatment at 67.5° C to effect a 6.0 $\log_{10}$ reduction.[179] The foregoing considerations suggest that thermization of heavily contaminated raw milk could lead to hazardous dairy products.[159] The heat-resistance of *Salmonella* spp. also increases with increasing concentrations of milk solids but decreases when the test strain is heated under reduced atmospheric pressure.[195]

45.8 PRINCIPLES OF DETECTION AND ISOLATION

45.8.1 Cultural Methods

The use of statistically significant sampling plans and sensitive analytical procedures are prerequisites for the successful identification of *Salmonella*-contaminated foods and agricultural products. The sampling plans of the International Commission on Microbiological Specifications for Foods (ICMSF) are based on the perceived degree of hazard associated with the distribution and consumer handling of a food, and on the desired stringency in assessing product safety.[351] Sampling plans define the number of replicate samples (n) to be taken at random from a production lot and the acceptance criterion (c), which corresponds to the maximum number of positive replicate samples that would be tolerated and not engender lot rejection. A zero tolerance ($c = 0$) for *Salmonella* has been proposed for all food categories.[351] *Salmonella* testing is a qualitative decision process that corresponds to a two-class attribute sampling plan whose stringency can be increased by adjusting the value for n and/or c. The use of analytical units greater than the 25g portions recommended in conventional methods also would increase stringency through enhanced method sensitivity.[14,168,240,350] Dry or wet compositing can markedly reduce the workload in the analysis of replicate samples from one or more lots of product.[160] In dry compositing, up to 15 × 25g analytical units can be combined into a single test. Thus, a lot of product examined with a stringency of $n = 60$ would be represented by a total of four test composites. A positive composite would signify that one or more of the pooled units was contaminated. Identification of the adulterated unit(s) within the positive composite would rest on the repeated analysis of individual units. In wet compositing, no more than 10 × 1 ml portions of preenrichment cultures should be combined into a single test for enrichment in a selective broth medium. The consecutive use of dry and wet compositing is not recommended because it would likely undermine method sensitivity.[157,160]

Conventional cultural methods for the detection of foodborne *Salmonella* consist of five distinct analytical steps.[14,168,240,350] These include nonselective enrichment (preenrichment) and selective enrichment in broth media, isolation of suspect *Salmonella* colonies on differential agar media, biochemical screening, and serological confirmation of isolates. Preenrichment allows the resuscitation of low numbers of stressed or injured salmonellae.[160,165] All test materials should be preenriched, including samples suspected or known to contain high levels of background microflora. The equivalence of buffered peptone water (BPW),[168,350] lactose,[14,240] and nutrient[168] preenrichment broths to more complex sterility testing media suggest that the nutrient requirements for successful preenrichment are minimal.[157,167] The choice of lactose broth for the preenrichment of commonly lactose-negative *Salmonella* strains remains paradoxical. Preenrichment in lactose broth in which the final pH of the preenrichment culture was 4.4 gave a lower recovery of salmonellae from cheese than preenrichment in a similar non-lactose containing medium in which the final pH was 5.7.[326] These findings contrast with the equivalence of nonbuffered lactose broth and BPW in the detection of salmonellae in raw egg products, frozen vegetables, and animal feed where the final pH of the lactose and BPW preenrichment cultures ranged from 3.8 to 5.9, and 4.8 to 6.9, respectively.[160] Although the progressive acidification of lactose preenrichment cultures to pH ≥ 3.8 is bacteriostatic and potentially lytic, the concomitant induction of the acid tolerance response (Section 45.7.2) would permit salmonellae to grow to detectable levels.

Next Page

Levels of 10^0 to 10^7 salmonellae ml^{-1} in overnight lactose and nutrient broth cultures reflect strain-specific responses and synergistic or antagonistic effects of food components and competitive microorganisms.[160,167] Surfactants including Tergitol-7 and Triton x-100 are used for the preenrichment of fatty foods.[14,175] The surfactants putatively liberate salmonellae from lipid micelles, allowing their proliferation in the aqueous phase; however, it has been suggested that the use of surfactants could lead to erroneous results arising from surfactant toxicity.[175] Preenrichment at elevated temperatures (41° C to 43° C) is not advisable because it introduces an additional stress under conditions designed to resuscitate debilitated *Salmonella* cells.[160,695] Attempts at cultural method brevity through short (6 to 8 hours) preenrichment have proven unsuccessful.[160,300] Short preenrichment does not favor bacterial proliferation and likely results in the transfer of low numbers of poorly resuscitated salmonellae into selective (toxic) enrichment media.[84,157,160,300] Prolonged (>24 hour) preenrichment may adversely affect the detection of foodborne salmonellae.[160,339] The volume of overnight preenrichment culture inoculated into selective enrichment broth did not alter method sensitivity where transfer volumes of 10.0, 1.0, and 0.1 ml were equally effective in detecting naturally contaminated foods and animal feeds.[157,160] However, with short (6 hour) periods of preenrichment, detection was transfer volume–dependent.[167] The use of 10 ml transfer volumes[350] does not improve method performance and, compared with other standard methods,[14,168,240] increases 10-fold the required volume of costly enrichment media. Direct enrichment has been applied to foods and agricultural products known or suspected to contain high levels of background microflora. The suspension of such materials into selective enrichment media (no preenrichment) was meant to repress the growth of nonsalmonellae and favor the outgrowth of salmonellae through reduced competition for nutrients. However, the low sensitivity of this approach seemingly stems from the direct contact of debilitated salmonellae with selective (toxic) conditions resulting in the death of the few *Salmonella* cells that frequently contaminate test materials.[157,160,624]

The enrichment of samples in selective broth media favors the growth of salmonellae through the inhibition of competitive microorganisms. Enrichment media including tetrathionate brilliant green (TBG), Rappaport-Vassiliadis (RV), and selenite cystine (SC) figure prominently in standard methods of analysis.[14,168,240,350] The use of the Hajna, Rolfe, and the two Mueller-Kauffman (North American and European) formulations of TBG, each with distinct levels of sensitivity, specificity, and buffering capacities warrants caution in the interpretation and interstudy comparison of experimental results. The selectivity of TBG stems from the tetrathionate ($S_4O_6^=$) anion formed from the reaction of thiosulfate ($S_2O_3^=$) with iodine. The molarity of $S_4O_6^=$ in the different TBG formulations ranges from 0.016 to 0.043.[157] Membrane-bound tetrathionate reductase in *Salmonella*, *Citrobacter*, *Serratia*, and *Proteus* affords protection against the $S_4O_6^=$-dependent inhibition of protein synthesis and the inactivation of active sites of enzymes.[160] The regular quality control of this and other selective and potentially toxic media is essential. The RV and TBG enrichment media are closely related in their use of RV and TBG triphenylmethane dyes as selective agents and their incubation at elevated (41° C to 43° C) temperatures. High concentrations of $MgCl_2$ further increase RV selectivity; however, the dependence of RV on a 1:100 transfer volume for the optimal recovery of foodborne salmonellae underlines the limited selectivity of this medium.[160,509,656,669,670] SC is a medium of low selectivity that is nevertheless important in the recovery of fastidious salmonellae that do not grow or grow poorly in TBG and RV media.[158,160] The selectivity of SC hinges on the more rapid uptake of selenite ($SeO_3^=$) by competitive microflora and the incorporation of inactivating seleno-polythionate analogs of sulfur-containing amino acids into enzyme proteins.[614] Growing human health concerns on the safe handling and disposal of SC are leading to its replacement with other enrichment media.[14] The incubation of TBG and RV at selective (41° C to 43° C) rather than permissive (35° C to 37° C) temperatures markedly increases method sensitivity by facilitating isolation of *Salmonella* on plating media.[157,160,372,605] SC is generally incubated at 35° C to 37° C because selenite-based media can be inhibitory to *Salmonella* at higher temperatures.[43,160] Comparative studies have ranked 16 to 24 hours enrichment conditions in the following decreasing order of effectiveness: $TBG_{43} \geq RV_{43} > TBG_{35} > SC_{35}$.[10,54,87,160,305,371,455,605] A minimum of two enrichment media and two incubation temperatures always should be used to optimize the detection of contaminated samples. For example, a combination of TBG_{43}/SC_{35} would be preferable to TBG_{43}/TBG_{35} or TBG_{43}/RV_{43} because it provides greater physiological latitude for the enrichment of *Salmonella* strains that poorly tolerate elevated temperatures or do not grow in media containing malachite green or brilliant green (BGA) dyes. The value of SC_{35} was evidenced in a major collaborative study where the medium uniquely identified 5.5% of 1,616 naturally contaminated foods and agricultural products.[175] The use of abbreviated (6 to 8 hours) enrichment has met with limited success because the approach undermines the full selective potential of enrichment media.[10,160,172] Prolonged incubation (≥ 48 hours) of enrichment media does not necessarily increase method sensitivity.[54,160]

Enrichment cultures are plated on differential and selective agar media that respond principally to the bacterial release of hydrogen sulfide or to acid production from discriminating substrates.[14,160,168,240,350] These agar media include BGA, brilliant green sulfa (BGS), xylose-lysine-desoxycholate (XLD), and Hektoen enteric (Hek) agars that respond to lactose and/or sucrose utilization.[160] The low selectivity of these media can be a problem because competitive strains can mimic *Salmonella* and result in costly and futile tests on suspect isolates. The occurrence of lactose- and/or sucrose-positive salmonellae limits the value of saccharide-dependent plating media.[160] Bismuth sulfite (BiS) agar is used widely because of its highly sensitive H_2S-detecting system and saccharide-independent differentiation of isolates.[156,160] Novel plating media include xylose-lysine-Tergitol-4 (XLT-4),[459,605] which is XLD with added Tergitol-4 for increased selectivity, Rambach agar,[268,365,369,396,512,543,605] and the ready-to-use SM-ID.[184,365,512] In addition to β-galactosidase activity, the Rambach and SM-ID media show acid production from propylene glycol and glucuronate, respectively. Suspect *Salmonella* colonies generally develop within 16 to 24 hours at 35° C to 37° C except on BiS, which may require 48 hours of incubation.[156,160,165] Reports on the sensitivity and specificity of plating media support the following ranking in decreasing order of effectiveness : BiS > BGS > BGA ≥ Rambach = SM-ID = XLT-4 > XLD > Hek.[160,184,605,680] The physiological diversity within the *Salmonella* genus necessitates the use of two or more plating media for the effective detection of the target microorganism in enrichment cultures.[158,160,334,680] The use of lactose and/or sucrose, the production of H_2S, and presence of lysine decarboxylase and urease are key determinants in the biochemical screening of presumptive *Salmonella* isolates.[14,168,350] Commercially available biochemical kits have proven invaluable in the identification of atypical salmonellae and taxonomically related microorganisms.[14,145,160] Nonetheless, confirmation of a presumptive *Salmonella* isolate rests on somatic (O) and flagellar (H) agglutination reactions using polyvalent and single grouping antisera. In contrast to somatic antisera, which may produce false-positive reactions with closely related nonsalmonellae, the highly specific flagellar (H) antisera provide for the conclusive identification of *Salmonella* strains.

Several cultural approaches promote the more rapid screening of *Salmonella*-negative samples. The Salmosyst® system combines nonselective and selective enrichment into a single analytical step through the progressive release of selective agents in the preenrichment broth culture. Following overnight incubation at 35° C, the enriched culture is inoculated onto appropriate plating media. Presumptive positive or negative results are thus obtained 24 hours earlier than with conventional cultural methods. Reported levels of agreement between the Salmosyst® and standard cultural procedures vary widely.[511,513,683]

The RV enrichment broth was reformulated to the modified semisolid Rappaport-Vassiliadis (MSRV) plating medium by increasing nutrient levels and selectivity through the addition of novobiocin.[191] Synergism between novobiocin, malachite green, acidity (pH 5.2), and the high concentration of $MgCl_2$ in MSRV plates effectively reduces the growth of background microflora. Following point-inoculation of MSRV with preenrichment (direct MSRV) or selective enrichment cultures following preenrichment (indirect MSRV), overnight incubation of the inoculated plating medium at 42° C to 43° C favors the radial migration of motile salmonellae. Growth from the perimeter of the zone of migration is then tested with polyvalent antisera and/or separated on differential *Salmonella* plating media for subsequent biochemical and serological characterization.[191] A minimum of 48 hours (direct MSRV) or 72 hours (indirect MSRV) is therefore required to obtain presumptive serological results. The threshold sensitivity of direct MSRV is 60 salmonellae per ml of preenrichment culture.[188] Nonmotile *Salmonella* strains yield false-negative results,[193,194,547] whereas related microorganisms such as *Enterobacter cloacae* and the holding of incubated MSRV plates at room temperature for several hours can produce false-positive results.[484,691] Studies on the sensitivity of direct MSRV indicate that the approach compares favorably with standard methods of detection and that the MSRV is more reliable with low- than with high-moisture foods (Table 45–21). The observation that indirect MSRV is only marginally superior to direct MSRV may stem from the use of short (8 to 12

h) periods of enrichment in selective broth media. The sensitivity of indirect MSRV increases significantly if longer (24 h) periods of enrichment are applied (D'Aoust, unpublished data). Of 100 naturally contaminated foods and agricultural materials, 88% were detected by direct MSRV, whereas 96%, 98%, and 91% were detected by indirect MSRV following 24 hours enrichment in TGB_{43}, TBG_{35}, and RV_{43}, respectively. Corresponding values for 6 h enrichment were 93%, 94%, and 81%, respectively.

In standard cultural procedures involving a preenrichment step, initiation of sample analysis is restricted to Mondays and Tuesdays if weekend work is to be avoided and if analyses are to be interrupted only by the refrigeration of incubated plating media. A novel refrigeration approach provides for the preenrichment of food samples on Mondays to Thursdays, inclusively. Following refrigerated (2° C to 10° C) storage of preenrichment and/or enrichment broth cultures over the weekend (72 h), the analysis of stored cultures is resumed on the next Monday. The sensitivity of the refrigeration approach varies with food groups. With high-moisture foods, the method detected, respectively, 88% to

95% and 91% to 100% of contaminated samples from the refrigerated preenrichment and enrichment cultures.[178,180] With low moisture foods, sensitivities of 99% to 100% and 99% to 100% were obtained.[171,178,180] The technique, which was recently recognized in standard methods,[14,168] is most valuable because it significantly increases laboratory flexibility and productivity.

45.8.2 Rapid Methods

Standard cultural procedures require 4 days to presumptively identify *Salmonella* in a test sample and up to 7 days to confirm the identity of the isolate.[165] This delays the release of foods and increases production costs. Efforts at greater method brevity have led to the commercialization of more than 30 diagnostic systems for the rapid detection of *Salmonella* spp. in food and agricultural products. These techniques insert in standard cultural methods at the level of preenrichment or after 6 hours (products with low numbers of background flora) or 24 hours (products with high numbers of background flora) of selective enrichment. Postenrichment cultures (18 and 6 hours) inoculated from 6 hours and 18 to 24 hours enrichment cultures, respectively, are used widely in rapid methodologies. Negative or presumptively-positive results are obtained 12 to 48 hours earlier than with conventional culture analyses.[165]

The detection of salmonellae by direct or indirect sandwich ELISA procedures hinges on the recognition of unique somatic (O) and/or flagellar (H) antigens by monoclonal or polyclonal antibodies (Table 45–22). ELISA procedures generally use microplates, strip wells, or dipsticks precoated with capture antibodies to specifically bind *Salmonella* antigens in test materials. The antigen-antibody complex then is revealed colorimetrically or fluorometrically by reaction with a specific peroxidase- or phosphatase-labeled conjugate and addition of enzyme substrate and chromogen. The threshold sensitivities of ELISA kits range from 10^4 to 10^6 salmonellae per ml of test culture with great disparity in kit specificity (Table 45–22). The strip-well Salmonella-Tek™ system (Organon Teknika, Durham, NC) relies on two monoclonal antibodies (MOPC 467 and 6H4), a peroxidase conjugate, and a H_2O_2/tetramethylbenzidine (TMB) chromogen system for the colorimetric detection of target antigens in heated M-broth postenrichment cultures. Validation studies using naturally and artificially contaminated foods and agricultural materials have reported false-negative rates of less than 6% and appreciably greater levels of false-positive reactions arising from the low specificity of the MOPC 467 antibody.[170] A major change in protocol in favor of enrichment at a high temperature (42° C) in the presence of novobiocin likely contributed to the enhanced specificity of the system in more recent studies.[165,217] Negative or presumptive-positive results are obtained within 50 to 56 hours following sample preparation. The manufacturer of Salmonella-Tek™ recently introduced the Capture-Tek™ format that detects salmonellae previously concentrated from preenrichment cultures by immunomagnetic separation using Dynal Dynabeads™ and subsequent enrichment of Dynabeads™ with adsorbed salmonellae in M broth supplemented with novobiocin for 5 hours at 42° C. The performance of this technique, which yields negative or presumptive-positive results in less than 30 h, has yet to be fully validated. In the Tecra™ visual immunoassay (Bioenterprises PTY Ltd, Roseville, NSW, Australia), *Salmonella* somatic and flagellar antigens in heated M-broth postenrichment cultures are captured on the surface of antibody coated strip- or microplate wells. The immune complex then is reacted with a peroxidase conjugate and revealed by the addition of enzyme substrate and azino-benzthiazoline sulfonate chromogen. Mean false-negative and false-positive rates of 3.8% and 7.3% (Table 45–22) with frequent identifications of *Escherichia coli*, *Citrobacter*, and *Enterobacter* as sources of false-positive reactions have been reported.[152,357] More recently, the Unique™ dipstick module was introduced by Bioenterprises PTY Ltd for the determination of salmonellae in overnight preenrichment cultures. A dipstick coated with capture antibody is moved sequentially through a six-compartment module, thereby providing for the immunoenrichment of the target organism in M-broth and its presumptive colorimetric identification from reactions of the capture antibody-antigen complex on the dipstick with an alkaline phosphatase conjugate and bromo-chloro-indoyl phosphate (BCIP) substrate. The system, which provides presumptive-positive results within 22 h of sample preparation, yielded false-negative and false-positive rates of less than 6.0% and 9.0%, respectively (Table 45–22). The Locate™ system (Rhône Poulenc Diagnostic Ltd., Glasgow, Scotland) is a microplate direct ELISA procedure that relies on monoclonal antibodies for the detection of somatic antigens in heated GN postenrichment broth cultures. Color development follows from the reaction of a peroxidase conjugate with substrate and TMB chromogen. Sample analysis is completed within 50 to 56 hours and the method provides good sensitivity and specificity (Table 45–22). The Equate™ direct microplate ELISA (Binax, South Portland, ME) requires less than 48 hours for the detection of *Salmonella* antigens in acid-treated M-broth postenrichment cultures. Immune complexes from the microwell reaction of precoated monoclonal antibodies and peroxidase conjugate with target antigens are revealed by the addition of enzyme substrate and TMB chromogen. Isolated reports on the performance of this system suggest good sensitivity but low specificity (Table 45–22). The microplate indirect Assurance™ assay (BioControl Systems Inc., Bothell, WA) uses proprietary polyclonal antibodies for the detection of *Salmonella* antigens in heated M-broth postenrichment cultures. Test configuration includes reaction of the immune complex consisting of targeted somatic (O) and/or flagellar (H) antigens and surface coated antibody with a second *Salmonella*-specific polyclonal antibody termed Assur-Link.™ The latter antibody minimizes stearic hindrance during the binding of the large enzyme conjugate polymer to the targeted microwell immune complex.[235] The capture antibody-antigen-Assur-Link™ complex is then reacted with a third polyclonal antibody-alkaline phosphatase conjugate followed by color development using a p-NO_2 phenyl phosphate substrate. Negative or presumptive-positive results are obtained within 50 hours of sample preparation. The Assurance™ assay yields low rates of false-negative and false-positive reactions (Table 45–22). The Vitek Immunological Diagnostic Assay System (Vidas™, bioMérieux sa, Marcy-l'Etoile, France) is an automated immunofluorometric system for the detection of *Salmonella* somatic (O) and flagellar (H) antigens in heated M-broth postenrichment cultures. This direct ELISA procedure relies on monoclonal (capture) and polyclonal (conjugate) antibodies for detection. One of the two principal components of the Vidas™ system is a solid phase receptable (SPR), a solid matrix in the shape of a pipette tip whose internal surface is precoated with capture antibody. The other component is a ready-to-use reagent strip that contains all the necessary reagents for in-line processing of the test sample. The reagent strip previously inoculated with heated M-broth culture and its corresponding SPR are seated in the instrument. The SPR is displaced successively into each of the 10 reagent chambers where reagents are automatically and repeatedly cycled into and out of the SPR. The intensity of blue fluorescence produced in the last chamber from the reaction of the conjugated alkaline phosphatase with methyl-umbelliferyl phosphate is then measured. The immunofluorescent assay including instrument interpretation of fluorometric results requires 40 to 50 minutes, whereas the entire test protocol is completed within 50 hours of sample preparation. Performance assessments of the Vidas™ system have yielded favorable results except for an unusually high level of false-negative reactions in one study that likely resulted from the use of short (6 hours) enrichment in RV_{42} and an inappropriate 1:10 preenrichment to enrichment transfer volume in the analysis of raw poultry samples.[151] *Citrobacter freundii* can produce false-positive Vidas™ reactions.[85]

Bacterial motility is used as a diagnostic tool in several technologies (Table 45–23). In the immunoimmobilization 1-2 Test™ (BioControl Systems Inc., Bothell, WA), motile salmonellae in selective enrichment cultures are presumptively identified within 50 hours of sample preparation. The assay hinges on the formation of a white precipitin band at the interface of salmonellae in a semi-solid medium and polyvalent flagellar (H) antisera diffusing toward the migrating target microorganism. The requirement for a single-reaction vial per test sample is cost effective because it prevents the waste of unused reagents as in precoated microwell ELISA. False-negative and false-positive rates of up to 10.6% and 5.1% have been reported in studies involving naturally and artificially contaminated test products (Table 45–23). The use of only one selective enrichment medium in the 1-2 Test™ protocol may limit test sensitivity particularly with products containing high levels of background microflora. *Citrobacter freundii, Enterobacter cloacae,* and *Klebsiella pneumoniae* may react in this assay.[679] The Oxoid Salmonella Rapid Test (Unipath Limited, Basingstoke, UK) is a 43-h test procedure that presumptively identifies motile salmonellae in preenrichment cultures using discriminant biochemical reactions. The system consists of two tubes each separated into an upper and lower chamber by a porous partition. The lower chamber of each tube contains different selective enrichment broth media. The upper chamber of one tube detects H_2S gas formation, whereas the upper chamber of the second tube monitors H_2S formation and acid production from lactose. Observation of such reactions in either or both upper chambers is indicative of the presence of salmonellae. Clearly neither of these systems will detect nonmotile *Salmonella* and the occurrence of atypical biotypes may have affected the performance of the Oxoid test system (Table 45–23).

The application of conductimetric, DNA hybridization, and immunodiffusion principles has resulted in innovative techniques for the rapid detection of foodborne salmonellae. The Malthus™ conductimetric assay presumptively identifies *Salmonella* in preenrichment cultures within 54 hours of sample preparation using paired conductance liquid media (SS_1 and SS_2). This automated system measures the change in electrical conductance associated with increasing concentrations of ionic species attributed to *Salmonella*-specific acid production from dulcitol and reductase-dependent conversion of trimethylamine oxide to trimethylamine (SS_1), and production of cadaverine from the decarboxylation of lysine (SS_2). Although SS_1 and SS_2 contain SC as selective agent, both media can give false-positive reactions with *Citrobacter* and *Hafnia alvei*, respectively.[214,487] High false-negative reaction rates and low specificity have also been reported (Table 45–24). Preliminary results with novel conductance media (M_1 and M_3) of enhanced selectivity from the addition of antibiotics and incubation at elevated temperature are encouraging.[92] Several DNA-based methods have been developed for the detection of bacterial pathogens, including the GENE-TRAK™ (GENE-TRAK Systems, Framingham, MA) assay for foodborne *Salmonella*. The system presumptively identifies salmonellae in Gram-negative postenrichment cultures within 50 hours of sample preparation. GENE-TRAK™ relies on synthetic capture and detector oligonucleotide DNA probes that hybridize to proximal but different *Salmonella*-specific ribosomal RNA sequences. The detector probe consists of a 35 to 40 nucleotide sequence labeled at both the 3' and 5' ends with fluorescein, whereas the capture probe of approximately 30 nucleotides contains a polydeoxyadenylic (poly-dA) tail attached to the 3' end of the probe sequence. A dipstick coated with a homopolymer of thymidine residues (poly-dT) is used to retrieve the [capture probe-rRNA-detector probe] complex from the reaction mixture. The complex then is reacted with a polyclonal antifluorescein antibody conjugated to horseradish peroxidase followed by color development using H_2O_2 and TMB chromogen. The combined results of eight validation studies showed mean rates of false-negative and false-positive reactions of 2.0% and 1.6%, respectively (Table 45–24). The reasons for the unusually high rate of false-negative reactions with artificially contaminated feeds are uncertain.[676] To fur-

ther simplify its analytical protocol, GENE-TRAK™ recently altered the configuration of the detector probe by replacing the fluorescein label and antifluorescein peroxidase conjugate with a direct labeling of the detector probe with peroxidase. The Path-Stik™ (Lumac B.V., Landgraaf, The Netherlands) is an immunochromatographic technique for the presumptive identification of salmonellae in BPW postenrichment cultures within 50 h of sample preparation. The appearance of a blue line in the test area of the Path-Stik™ dipstick results from the capillary comigration and reaction of target antigen with colored latex particles coated with *Salmonella*-specific antibody and capture of the migrating antigen by a second *Salmonella*-specific antibody immobilized in the test area. Results with the Path-Stik™ test (Table 45–24) clearly indicate the need for improved sensitivity possibly through greater selectivity of the enrichment protocol and enhanced antibody affinity for *Salmonella* antigens.

Several novel technologies are available whose performance has yet to be fully evaluated. The Bacterial Ice Nucleation Detection (BIND™) system (Idetek Inc., Sunnyvale, California) is a microplate colorimetric assay for the detection of salmonellae in overnight preenrichment or direct enrichment cultures. The system, which yields negative or presumptive-positive results in less than 24 hours, is based on a *Salmonella*-specific phage transduction of an ice nucleation activity (*ina*) gene that encodes a template protein for the formation of ice crystals.[697] The transduction and synthesis of nucleation proteins by *ina*$^+$ salmonellae are detected by the microwell freezing (−9.3° C) of a carboxyfluorescein dye (orange-red), whereas no change in the green fluorescent dye confirms the absence of *Salmonella* in the test sample. Preliminary results from the manufacturer indicate a threshold sensitivity of ≥200 salmonellae per milliliter and high specificity of the BIND™ technique. The polymerase chain reaction (PCR) is a sensitive and specific technique for the amplification of a target sequence of nucleic acid.[302] The procedure generally involves alternate cycles of heat denaturation of double-stranded DNA into single strands, annealing of oligonucleotide primers to a region in the single-stranded DNA that flanks the targeted sequence, and use of a thermostable *Taq* polymerase to replicate the targeted sequence. Potential problems with this technology include inhibition of the polymerase reaction by food components, positive PCR responses from nonviable target microorganisms, and environmental cross-contamination of test samples or pre-amplification reagents. Interest in the application of PCR technol-

ogy (Chapter 64) already has produced three commercial diagnostic products for the detection of foodborne *Salmonella*. The BAX™ system (DuPont Company, Wilmington, Delaware) provides presumptive evidence of salmonellae in overnight preenrichment cultures within 30 h of sample preparation. Following the separation of PCR products by gel electrophoresis, the identity of *Salmonella*-specific amplicons is confirmed by comparison with electrophoretic control bands. Preliminary results (May 1996) from a study by Campden and Chorleywood (Chipping Campden, UK) indicated a threshold sensitivity of 10^2 to 10^3 salmonellae ml^{-1} of pure culture and high levels of sensitivity in the detection of *Salmonella* in inoculated and naturally contaminated foods. The Probelia™ system (Sanofi Diagnostics Pasteur, Marnes La Coquette, France) is a colorimetric PCR technique for the presumptive identification of *Salmonella* in overnight preenrichment cultures. The *iagA* gene within the *Salmonella* invasion apparatus is amplified, and PCR products are captured in microwells precoated with a specific probe. The resulting probe-PCR product complex is revealed by reaction with a amplicon-specific peroxidase-labelled probe and addition of enzyme substrate and TMB chromogen. Preliminary results from the manufacturer underline the unfailing sensitivity and specificity of the Probelia™ technique. The TaqMan™ system (Perkin-Elmer Biosystems, Foster City, California) is an automated fluorometric procedure for the determination of salmonellae in preenrichment cultures within 24 hours of sample preparation. PCR amplification of the targeted *invA* gene is detected by a fluorogenic probe covalently labelled with a 5'-reporter and a 3'-quencher dye. The proximity of the reporter and quencher dyes in the intact probe suppresses fluorescence, whereas enzymic cleavage of the fluorogenic probe results in increased fluorescence. In the TaqMan™ assay, primers hybridize to the targeted *invA* sequence, which is then amplified by the AmpliTaq DNA polymerase in a 5' to 3' replication process. During amplification, the fluorogenic probe binds to an alternate target sequence within the generated PCR fragment but is subsequently hydrolyzed by the 5'-nuclease activity of the AmpliTaq DNA polymerase, thereby releasing the reporter dye and increasing the fluorescence signal. Pure culture studies conducted by the manufacturer indicate a product sensitivity and specificity of 99.7% and 100%, respectively.

The last decade has witnessed the development of numerous methods for the rapid detection of foodborne *Salmonella*. Although ELISA kits (Table 45–22) readily detect salmonellae belonging to somatic groups B to E, the ability of these kits to detect exotic serovars that are found increasingly in foods imported from Third World countries has yet to be ascertained. Moreover, foodborne *Citrobacter, Enterobacter,* and *Escherichia* may yield false-positive reactions. The uncertainty surrounding the current and future prevalence of nonmotile salmonellae and the impact of environmental conditions on the synthesis of functional flagella detracts from methods that depend on bacterial motility (Table 45–23). The reliance of PCR and probe (Table 45–24) technologies on stable genomic loci augurs favorably for the future development of sensitive, specific, and cost-effective methodologies for the detection of foodborne *Salmonella*.

45.9 CONTROL

The ubiquity of *Salmonella* in the natural environment and the disquieting increased incidence of antibiotic-resistant salmonellae emphasize the public health importance of stringent controls on the production, processing, and distribution of foods and food ingredients. The control of *Salmonella* in meat animals and meat products presents a formidable challenge because of the complex organization of the meat industry and numerous opportunities for product contamination within the farm to retail continuum.[703] The intensive husbandry practices used in the bovine, porcine, and poultry meat industries promote intestinal carriage and surface contamination of live animals.[160] The problem is likely to be further compounded by the spread of untreated sludge and animal waste on farmlands, which contaminates surface waters and exposes grazing herds to infection. Stress-induced shedding of *Salmonella* as a result of food or water deprivation, prolonged holding in lairage pens, induced molting, and transport of live animals to slaughtering plants further increase the surface contamination of meat animals.[316,468,469] The inability to consistently produce *Salmonella*-free replacement stocks and animal feeds (Table 45–6) results in a pyramidal increase in animal infection and exacerbates control efforts within the red meat and poultry industries.[160,690] For example, the introduction of day-old chicks from an infected multiplier breeder flock in freshly sanitized poultry houses and provision of contaminated feeds would likely negate the anticipated benefits of Hazard Analysis Critical Control Point (HACCP) control measures and good farming practices, such as disinfestation and biosecurity of rearing premises, controlled access to poultry houses, provision of clean drinking water, and control of airborne contamination. Improvements in the bacterial quality of rendered meat products depend on strengthening of in-plant sanitary practices and process controls, replacement of aging equipment with more efficient units that can be easily dismantled and sanitized, physical isolation of raw meat processing areas, and protection of thermally processed materials from recontamination.[160,186] Although conventional steam conditioning of feeds at 82° C or greater prior to pelleting constitutes a positive step toward *Salmonella*-free feeds, recontamination of finished products during feed mill operations, bulk storage, transportation, and on-farm storage needs to be more effectively controlled.[143,319,703] The greater agricultural use of feeds treated with Bio-Add™ (Trouw UK Ltd, Norwich, UK) or Sal Curb™ (Kemin Europa N.V., Herentals, Belgium) mixtures of formic and propionic acids or with other nonantibiotic additives to inhibit or inactivate secondary contaminants would improve product safety.[73]

Vaccines are an important on-farm measure to combat *Salmonella* in animal husbandry.[160,703] Parenteral live or killed vaccines for protection against *S.* Gallinarum (poultry), S. Enteritidis (poultry), S. Dublin (bovine), *S.* Choleraesuis (porcine), and *S.* Typhimurium, which indiscriminately infects farm animals, are available. These animal vaccines afford little or no cross-protection against other *Salmonella* serovars. The use of genetically defective mutants ensures that live vaccines are avirulent.[114,138,674] Competitive exclusion of salmonellae in layer and broiler flocks is based on the ability of orally administered cultures prepared from the fecal or cecal microflora of *Salmonella*-free adult birds to protect chicks against *Salmonella* intestinal colonization.[622] The unknown composition of these probiotic mixtures of facultatively and strictly anaerobic microorganisms poses major problems in terms of vaccine standardization and raises concerns about the possible presence of avian pathogens. The protective capacity of these mixes largely has been assessed in laboratory scale experiments involving the oral treatment of day-old chicks with the protective mixture and oral challenge of treated birds with *Salmonella* on the following day. The efficacy of treatment is assessed in terms of the prevalence of *Salmonella* in necropsied tissues of control and treated birds euthanized 10 or more days following challenge. Several field studies in Europe and North America indicate that the use of undefined mixtures coupled with good hygienic practices on poultry farms do not consistently reduce *Salmonella* in commercial poultry flocks.[622] Undefined mixtures marketed under the trade names of Broilact™ (Orion Corporation Farmos, Turku, Finland) and Aviguard™ (Life-Care Products Limited, Malvern Link, England) are currently available.[90,622] Attempts to develop defined mixtures that effectively protect breeder and broiler birds against *Salmonella* infec-

Next Page

tion have met with limited success.[622] The addition of vermicompost, an earthworm-dependent digest of adult chicken feces, to the feed of newly hatched chicks afforded protection against *Salmonella* colonization.[618]

Many operations in bovine and porcine slaughterhouses contribute to carcass contamination.[76,93,201,703] The removal of animal hides and fleece soiled with fecal material and the scalding, dehairing, and polishing of pork carcasses greatly favor cross-contamination of meat surfaces.[201,272,703] In addition to the use of a steam vacuum to dislodge and aspirate feces and ingesta from hide surfaces,[41] thermal or chemical decontamination of scald water prior to its recycled use in the dehairing process[272] would enhance meat quality and safety. Sanitizing meat carcasses by immersion or spray-washing with cold and hot water, chlorine, chlorine dioxide, quaternary ammonium compounds, trisodium phosphate (AvGard™), ozone, hydrogen peroxide, and organic acids is well documented.[155,201,202,283,532,533] Hot (74° C) water,[283] hot (65° C to 80° C) chlorinated water,[8] and hot (53° C to 55° C) dilute acetic or lactic acid spray-washing of carcasses are gaining favor over the more traditional temperate water rinsing of eviscerated meat carcasses.[201,532] Spray decontamination of carcasses is preferable to immersion because the full potency of bactericidal agents is retained and not reduced by the suspended organic debris in wash-water tanks. Innovative equipment for the steam pasteurization of eviscerated beef carcasses gradually is being introduced into North American slaughterhouses.[40] The merits of other sanitizing technologies such as gamma and electron irradiation, electromagnetic waves, and pulsed electric or magnetic fields have also been considered.[141]

The hygienic slaughter of poultry is difficult because of the intestinal carriage of *Salmonella* in asymptomatic birds and surface fecal contamination of birds arriving at the abattoir. In conjunction with common feed withdrawal practices,[703] the use of properly sanitized transport crates,[218,559] and reduction in the number of birds per crate to reduce shipment stress would markedly reduce contamination of bird surfaces. Commercial scalding at 52° C to 60° C for up to 2 min and the defeathering of bird carcasses constitute weak links in the hygienic processing of poultry. The serial passage of fecally soiled birds in scald tanks and limited replacement of contaminated scald waters result in widespread cross-contamination of birds. Immersion scalding at temperatures exceeding 60° C is contraindicated because it damages the protective (hydrophobic) keratinized epidermal layer of the poultry skin and enhances the attachment of salmonellae to underlying tissues.[134,387,611] A similar condition prevails in the kosher process where cold (7° C) scalding necessitates a lengthy defeathering process that damages poultry skin and encourages bacterial attachment.[134,385] Acidification of scald water with organic acids yields carcasses that are unacceptable organoleptically.[421] Immersion tank scalding at pH values of 9.0 to 11.0, scalding in tanks operated under counter-current flow, successive scalding in three immersion tanks regularly replenished with fresh water, steam scalding of birds on the conveyor line, simultaneous scalding and plucking using a hot (62° C) water spray and final washing of scalded birds with chlorinated water, cetylpyridinium chloride, and other bactericidal agents have been advocated for greater reduction of *Salmonella* on poultry carcasses.[38,160,340,386,470] Following defeathering and evisceration, carcasses are cooled in counter-flow immersion chill tanks (spin chillers) or in a stream of cold air.[160,419] Other possible chill technologies of interest include cryogenic chilling with liquid nitrogen or solid carbon dioxide and evaporative chilling resulting from the vacuum evaporation of moisture on warm carcasses.[419] Comingling of large numbers of carcasses in spin chillers contributes to cross-contamination, which depends greatly on the level of salmonellae on eviscerated birds entering the spin chiller.[419] Several bactericides including chlorine, chlorine dioxide, organic acids, propylene glycol, and ozonation of recycled chill waters have been proposed for the reduction of *Salmonella* in chill water.[354,418,419,642] The ability of the AvGard™ trisodium phosphate wash solution to decontaminate carcasses and to effect a 2.0 $\log_{10}$ or greater reduction in surface *Salmonella* contamination putatively stems from its highly alkaline pH rather than a cleansing action of the inorganic salt.[139,420,708] Seemingly, the alternate use of NaOH to attain high pH values would be equally effective without raising environmental concerns on the disposal of insoluble phosphates in spent AvGard™ solutions.

Effective intervention strategies in the shell egg industry are needed to reduce the ongoing human pandemic of *S.* Enteritidis infections. Control measures include *Salmonella*-free replacement layer birds, probiotic and vaccine prophylaxis, *Salmonella*-free feeds with added nonantibiotic preservatives, and stringent biosecurity in layer farm operations. In addition to the traditional washing of shell egg surfaces in warm water adjusted to pH 10.0 or greater,[329,464] other bactericidal wash treatments using chlorine, organic acids, trisodium phosphate, iodophore, or H_2O_2, as well as ultraviolet irradiation have been considered for surface decontamination.[284,336,397,398,464] Prompt refrigeration of graded shell eggs and their cold storage (7° C or lower) during distribution and retail display would retard the growth of internalized salmonellae. The diversion for pasteurization of shell eggs from layer flocks infected with *S.* Enteritidis would improve public health safety.[11,447] A recently marketed in-shell pasteurization system that reportedly effects a 5.0 $\log_{10}$ reduction of salmonellae in egg magma from the immersion of intact shell eggs in a water bath held at 56° C (Pasteurized L.P.™, Laconia, NH) is most promising. A similar lethality was reported for shell eggs held in a hot air oven (55° C) for 3 hours.[336]

The growing importance of fresh fruits and vegetables as infectious vehicles of *Salmonella* and other bacterial and parasitic disease agents warrants a strengthening of hygienic practices in the production, distribution, and marketing of these ready-to-eat products. The agricultural use of clean irrigation water, treatment of animal wastes before use as fertilizer, and education of field workers in personal hygiene and hygienic handling of fresh produce would greatly alleviate the health risk associated with these products.[96,345] Postharvest wash waters containing chlorine, ClO_2, organic acids, trisodium phosphate, H_2O_2, and surface coating of fresh produce with a shellac-based water wax reportedly reduce surface contamination of fruits and vegetables.[499,585,685,715,717] Cold shipment of produce in refrigerated vehicles or on ice made from hyperchlorinated water is highly recommended. Decontamination of sprouting seeds requires prolonged soaking in chlorinated water, calcium or sodium hypochlorite, H_2O_2 or ethanol, or the heating of seeds in a water bath for 5 minutes at 57° C.[82,356] Modified or controlled atmosphere packaging extends product shelf-life by replacing air with high concentrations of CO_2 mixed with N_2 and/or O_2 to inhibit the growth of aerobic spoilage microorganisms.[162,335] The approach neither promotes the growth nor adversely affects the survival of *Salmonella*.[162] Bacteriostasis is also favored by the cold storage of packaged fruits and vegetables at low relative humidity. Consumers and handlers in food service and retail food establishments should be aware of the health hazards from the unrefrigerated storage of cut produce, which exposes plant tissues to bacterial invasion and proliferation.[49,226,280,422,716]

Aquaculture is a relatively new food industry where six of the nine major producers operate in Asia, led by the People's Republic of China with an approximate output of 4.0 × 10^6 metric tons in 1985.[625] The prevailing hygienic conditions in these countries potentiate the contamination of unprotected rearing ponds and aquacultural products with human pathogenic microorganisms.[163,164] Feeding of reared species with raw meat scraps, animal feed, poultry manure, and human excrement exacerbates public health risks.[423,550,551] These concerns are compounded by the widespread on-farm use of antimicrobials where accumulation of excess drugs in pond sediments selects for antibiotic-resistant bacteria.[50,103,164] The occurrence of resistant strains in cultured fish attests to the hazard of this aquacultural practice.[196,307,582,657] Moreover, a growing industrial application of the newer quinolones and fluoroquinolones for therapy and prophylaxis is disquieting because it favors the emergence of bacterial pathogens that exhibit cross-resistance to medically important fluoroquinolones. The spectre of bacterial quinolone-resistance in aquacultural products that frequently are cooked lightly prior to consumption reinforces the need for more stringent hygienic controls and a ban on the prophylactic and therapeutic use of fluoroquinolones in aquacultural operations in developed and in Third World countries. The increasing use of antimicrobials on fruit and vegetable crops is yet another public health concern, although the impact of this horticultural practice has yet to be assessed.

Government endorsement of irradiation for the reduction of spoilage microflora and the elimination of human bacterial pathogens in foods and food ingredients has provided the industry with a technology that promotes greater food safety and shelf stability (Chapter 4).[147,467] Irradiation exerts little or no adverse effects on the nutritional value and wholesomeness of irradiated foods.[273] From the early application of gamma irradiation to disinfest and inhibit sprouting of vegetable crops, numerous studies have confirmed the efficacy of radiation doses greater than 3.0 kGy to eliminate *Salmonella* in foods.[130,204,479,641] However, irradiation does not effectively destroy preformed bacterial toxins. In spite of conclusive evidence and assurances from the World Health Organization that low to medium doses of irradiation do not adulterate foods with potentially harmful radiolytic additives,[147] consumer apprehension on the safety of this bactericidal treatment remains an important hurdle in the successful marketing of irradiated foods.[535]

The continued prominence of human foodborne salmonellosis and clear evidence that this major health problem is increasing globally reiterates the need for concerted control efforts in all sectors of the food chain. The urgency of the situation is fueled by the pandemic spread and persistence of highly virulent strains such as S. Enteritidis and S. Typhimurium DT 104, the identification of new infectious food vehicles, and an alarming rise in foodborne *Salmonella* exhibiting multiple resistance to medically important antimicrobial drugs. Improvements in meat animal husbandry through the on-farm placement of noninfected stocks and provision of *Salmonella*-free feeds strengthened by improved hygienic slaughter of meat animals are essential. Efforts of the food industry to improve the quality and safety of food products continue to be undermined by the hazardous preferences of some consumers for raw milk cheese (Table 45–17), certified raw fluid milk,[529,637,686] raw fish (sushi) and bivalves, and raw minced beef crowned with raw eggs (steak tartare) that clearly defy logic, social responsibility, and self-preservation. Consumer education on the safe handling and cooking of foods remains a formidable challenge for the next century.

46.1 INTRODUCTION

Shigellosis, also known as bacillary dysentery, is an illness characterized by watery diarrhea, which is followed within a few days by the appearance of mucus in the stool, with or without blood. In 1898, a bacterium was isolated and characterized from a patient with bacillary dysentery by the Japanese bacteriologist Kiyoshi Shiga.[96] A few years later, work by Flexner[24] led to the isolation of a serologically related bacterium in the stools of patients with dysentery. Conradi[15] and Neisser and Shiga[72] indicated that a toxin (subsequently named Shiga toxin) may be responsible for pathogenesis. In 1950, the bacillus isolated by Shiga, *Bacillus dysenteriae*, was renamed *Shigella dysenteriae*.

Shigellosis is a diarrheal disease that affects millions of people yearly, not only in developing countries but also in industrial countries. Rapid spread of the disease can occur in crowded living quarters throughout the world, particularly in countries lacking the infrastructure to maintain proper sanitation. In developed countries, changes in lifestyle have led to increased numbers of day-care centers and nursing homes. Individuals in these facilities are at increased risk from the rapid dissemination of *Shigella*. Interestingly, diarrheal diseases, including those caused by *Shigella*, are sometimes a significant factor in military campaigns. In Saudia Arabia in 1991, 57% of United States (US) troops experienced diarrhea; the pathogens most frequently isolated from stool samples (432) were enterotoxigenic *Escherichia coli* (30%) and *Shigella* (26%).[40] Shigellosis can affect large segments of civilian populations by events such as civil war and the displacement of people into refugee camps as in Rwanda.[78] In 1993, an outbreak of bacillary dysentery in Mozambique affected 47,483 individuals, with 199 fatalities reported. *S. dysenteriae* type 1, apparently the leading cause of shigellosis in Africa, was identified as the pathogen responsible for this epidemic.[3]

Foodborne outbreaks of shigellosis occur worldwide and, in some instances, affect more than one country. A recent outbreak in several European countries was caused by consumption of contaminated lettuce imported from Spain.[27,47] Research into methods for the identification of sources of foodborne outbreaks by *Shigella* lag behind the technology developed for the clinical laboratory. Foods

potentially at risk are not routinely screened for *Shigella* because this pathogen is spread principally by person-to-person contact and is not associated with any specific food.

LaBrec[54] demonstrated in 1964 that shigellae have the ability to invade epithelial cells; this was established as an essential step in the pathogenesis of bacillary dysentery. An important observation in elucidating the molecular events of *Shigella* pathogenesis was the correlation of the presence of a 180 to 220 kilobase pair (kbp) plasmid and the ability of *Shigella* to invade colonic epithelial cells.[87,88] Many of the plasmidborne genes responsible for pathogenesis of *Shigella* have been identified, sequenced, and characterized. The exact nature of the way in which these genes and the proteins they encode interact with the host environment and with each other has not been elucidated fully, although some models have been proposed.[126]

46.2 TAXONOMY AND CHARACTERISTICS OF THE ORGANISM

The genus *Shigella* contains four species that are Gram-negative, rod-shaped bacteria; it is taxonomically grouped in the family Enterobacteriaceae. The four species can be differentiated from each other by the fermentation of sugars, sugar alcohols, production of indole, and the synthesis of ornithine decarboxylase or arginine dehydrolase. Although these organisms are reported to be nonmotile, in a recent report, all four *Shigella* spp. (virulent and avirulent strains) were shown not only to possess flagella but also to be motile in low-percentage soft motility agar.[30] Members of the genus *Shigella* are genetically, biochemically, and serologically similar to *E. coli.*[12] One major difference between the two is the inability of *Shigella* to ferment lactose (although some do ferment lactose slowly). Most *E. coli* are lactose fermenters although enteroinvasive *E. coli* (*EIEC*), a causative agent of bacillary dysentery, is also a lactose nonfermenter. *Shigella* spp. are unable to produce gas during the fermentation of carbohydrates and cannot use citrate as a sole source of carbon.[13] Table 46–1 summarizes some of the biochemical tests used to differentiate *Shigella* from *E. coli.*

EIEC share many similarities with *Shigella*, ie, they contain the large virulence plasmid necessary for pathogenesis and possess an O-antigen, such as *EIEC* O124, that cross-reacts with several serotypes of *Shigella*. In this case, the identification of the causative agent in a foodborne disease incident can be difficult. For example, in an outbreak caused by *EIEC*-contaminated soft cheese, the initial identification was misdiagnosed as *Shigella.*[112] A significant difference between *EIEC* and *Shigella* is the infective dose; in *EIEC*, it is 10^6 bacteria and for shigellae, it is only 10 to 10^2 organisms.[19] The molecular events that are responsible for the difference in infectious doses are not known.

Table 46–1 Biochemical Reactions To Distinguish *Shigella* spp. from *E. coli*

	Result	
Test	Shigella	E. coli
Motility	–	+
D-glucose gas production	–*	+
Lactose acid production	–†	+
Mucate fermentation	–	+
Lysine decarboxylase	–	+
Christensen citrate	–	D
Acetate	–	+

* Strains of *S. flexneri* serovar 6 and *S. boydii* serovar 13 and 14 are positive.

† Strains of *S. flexneri* serovar 2a, *S. boydii* serovar 9 are positive, and *S. sonnei* are positive after a few days.

D: differrent reactions

Bacillary dysentery is caused by all four members of the genus *Shigella*, which are grouped serologically as follows: *S. dysenteriae* (group A), *S. flexneri* (group B), *S. boydii* (group C), and *S. sonnei* (group D) (Table 46–2). Groups A through C are further divided into more than 45 serotypes and subtypes based upon the O-antigens of the lipopolysaccharide (LPS). *S. sonnei* is the only group that has a single serotype. The range of severity of illness elicited by the various species correlates with their serogroup and a correlation seems to exist between serotype and geographical location.[52] Thus, *S. dysenteriae* is associated with the most severe symptoms of illness and generally occurs in the least developed countries. This pathogen is the only etiological agent of epidemic dysentery; between 5% and 15% of these cases are fatal, with children under the age of 5 having the highest rate of fatality. *S. sonnei* causes the least severe symptoms and is found in the more industrialized countries. *S. flexneri* usually is observed in developing countries and may cause mild to severe infections. *S. boydii* also causes mild to severe illness but rarely is isolated in developed countries and is found most often in the Indian subcontinent.

Table 46–2 Characteristics of *Shigella* species

Organisms	*Serotype*	*Geographic Distribution*	*Distinguishing Characteristics*
S. dysenteriae	Group A	Indian subcontinent, Africa, Asia	Produce Shiga toxins, cause most severe cases of dysentery, high mortality rate if untreated
S. flexneri	Group B	Most common isolate in developing countries	Less severe symptoms of dysentery
S. boydii	Group C	Rarely isolated in developed countries	Biochemically identical to *S. flexneri*, distinguished by serology
S. sonnei	Group D	Most common isolate in developed countries	Produces mildest form of shigellosis, single serotype

46.3 CHARACTERISTICS OF THE DISEASE

In general, shigellosis is a self-limiting disease, lasting 5 to 6 days if untreated; however, in young malnourished children, the elderly, and the immunocompromised (eg, acquired immunodeficiency syndrome patients),[98,118] the disease may be fatal. It is estimated that shigellosis is responsible for the death of 500,000 children worldwide each year.[8]

Clinical symptoms of shigellosis range from watery diarrhea to severe dysentery. Usually the individual has abdominal pain, which is accompanied by the appearance of mucus, blood, and polymorphonuclear leukocytes in the stool within 2 days after the onset of diarrhea.[20] Fever develops in approximately 50% of infected individuals. The illness can progress to a severe ulcerative colitis with hypotensive shock and death.[75] The incubation period following ingestion of *Shigella* is typically 1 to 4 days, depending on the strain involved and the number of organisms ingested.

The dysentery phase of illness, characterized as the passage of stools containing blood and mucus, generally is preceded by watery diarrhea 8 to 12 hours beforehand. Watery diarrhea is most likely due to jejunal secretion that is not reabsorbed by the colon because of bacterial damage to the colonic mucosa.[51,84] The dysentery stage of the disease is associated with more extensive bacterial invasion and destruction of colonic epithelial cells. As the disease progresses, areas of invasion in the colon are expanded with the spread of shigellae to adjacent cells. Areas of necrosis result in the release of dead epithelial cells and blood into the colon.[118] Organisms rarely infiltrate beyond the lamina propria, and septicemia or bacteremia seldom occur.[75] Invasion of the colonic epithelial cells appears to be necessary for illness to occur because genetically modified strains that are incapable of invasion do not cause dysentery in humans or in animal models.[28,59]

Other clinical manifestations can occur from infections due to certain *Shigella* species. Reactive arthritis or Reiter's syndrome may follow infections with *S. flexneri*.[8] Reiter's syndrome can include three clinical symptoms: urethritis, conjunctivitis, and arthritis. One possible explanation for these sequelae of shigellosis is that antibodies produced in response to antigens of *S. flexneri* cross-react with the human leukocyte antigen HLA-B27.[103] In one study, a small plasmid was reported to encode antigens structurally similar to HLA-B27.[107] Hemolytic-uremic syndrome (HUS) is caused by *S. dysenteriae* type 1 and other pathogens, notably enterohemorrhagic *E. coli* O157:H7. HUS is a common cause of renal failure in children. Although *Shigella* may be responsible for 5% to 15% of all cases of diarrhea worldwide, shigellae are associated with 30% to 50% of cases of dysentery. Other symptoms include thrombocytopenia and microangiopathic hemolytic anemia (see Chapter 43 for more detail).[48]

46.4 MECHANISM OF PATHOGENICITY

The mechanism for pathogenesis of *Shigella* infections is complex and is mediated by genetic factors similar to those of other bacterial pathogens. Much of the genetic information comprising the necessary components of *Shigella* pathogenesis is known but the function of each gene has not been completely elucidated. It is not the intent of this chapter to review in detail the complex genetics of *Shigella* virulence factors; this may be found elsewhere.[34,79]

Shigella spp. possess several key properties that are responsible for their virulence. The ingested microbes must survive the acidic environment of the stomach, which is the first significant host defensive barrier encountered by the bacteria. To produce clinical symptoms, shigellae must attach to and invade the epithelial cells of the colon, multiply intracellularly, and disseminate intercellularly through adjacent colonic epithelial cells. Although *Shigella* and most *Salmonella* spp. are enteroinvasive pathogens and share similar mechanisms of invading cultured cells, a notable difference is that internalized *Shigella* lyse endosomes and are found in the cellular cytoplasm.[89] In contrast, *Salmonella* do not lyse endosomes but multiply within them.[110]

Shigella species have a preference for M cells of the colon; these are specialized epithelial cells associated with mucosal lymphoid tissue.[80,126] After adherence to and uptake into colonic M cells, shigellae are engulfed by phagosomes and approximately 1.5 h later lyse the M cell vacuoles. The pathogen multiplies intracellularly and spreads intercellularly from the basolateral side into the submucosa of the colon. Further events are: (1) the interaction with host immune effector cells, (2) apoptotic lysis of macrophages, and (3) cytokine release and infiltration of polymorphonuclear leukocytes.[97,127]

46.4.1 Assays for Virulence

Monkeys have played a pivotal role in determining the pathogenesis of *Shigella*; however, these animals are expensive to maintain. Other animals can be used to measure certain phenotypical virulence properties of *Shigella* even though shigellae are not normal pathogens for these animals. Starved, opiated guinea pigs, fed orally with *Shigella*, have been used to show the invasive nature of this pathogen.[54] Another *in vivo* assay uses the ligated ileal loop of the rabbit to measure fluid secretion and tissue invasion.[54] The Séreny test[92] is probably the most widely used assay employed to demonstrate invasion and spread. The assay is performed by inoculating *Shigella* directly on the corneal surface of either a rabbit, guinea pig, or mouse. The development of keratoconjunctivitis indicates the ability of *Shigella* to invade the corneal epithelial cells, multiply, and spread to adjacent cells; these events mimic the invasion of colonic epithelial cells. Recently, adult rabbits were shown to display symptoms of clinical dysentery and characteristic histological changes associated with shigellosis after *S. flexneri* 2a was inoculated directly into the proximal colon.[82]

In vitro assays using mammalian cell lines, such as cultured HeLa or Henle cells, have facilitated research efforts to link biologic function to specific genetic loci of shigellae. Shigellae are able to invade and multiply within the cultured cells.[35,36,54] One version of these assays was developed to measure the ability of virulent *Shigella* to produce discrete plaques within the cultured monolayer.[76] This process parallels the invasion and multiplication stages that occur in colonic epithelial cells leading to localized infected cells and necrosis. The differential binding of the planar dye Congo Red by virulent strains of *Shigella* has been used to differentiate plasmid bearing and plasmidless cells. The genes necessary for Congo Red binding are located on the large virulence plasmid, and avirulent cells lacking this plasmid appear as white colonies on agar medium supplemented with Congo Red.[65]

46.4.2 Chromosomal Genes

The role of the *xyl-rha* region of the chromosome in intracellular multiplication of *Shigella* species was established by Falkow and colleagues using conjugational transfer of genes from *S. flexneri* 2A to *E. coli* K-12.[22] The *iucABCD* locus, which encodes aerobactin, an iron scavenger, and the *iutA* gene, whose gene product is an outer membrane receptor for this siderophore, are within this region. Aerobactin-negative mutants are invasive but exhibit a delayed reaction in the Séreny test. Most *Shigella* spp. except *S. dysenteriae* type I carry these biosynthetic and transport genes although some of these genes apparently are not expressed in *S. sonnei*.[57]

The exact role of LPS in *Shigella* pathogenesis has not been fully determined but it is thought to be a necessary component in intercellular spread to adjacent cells.[31,86] Strains that lack the O-antigen, yet still have either complete or incomplete LPS cores, are able to invade tissue culture cells but are negative in plaque assays and in the Séreny test. An important distinction between *Shigella* spp. is the location of the genes for LPS synthesis. In *S. flexneri*, the O-antigen biosynthetic genes necessary for LPS synthesis are encoded entirely on the chromosome and are located near the *his* locus. In *S. sonnei* and *S. dysenteriae*, however, synthesis of the O-antigen is plasmid-dependent. In *S. sonnei*, the 180-kbp virulence plasmid encodes a specific O-side chain of the LPS whereas in *S. dysenteriae* a 9-kbp plasmid and the large virulence plasmid are necessary for the complete synthesis of the O-side chain.

Temperature plays a critical role in controlling the expression of the virulence genes of *Shigella* spp. A chromosomal gene partly responsible for the temperature regulation of virulence gene expression is *virR* (*hns*).[66] At 30° C, *Shigella* spp. and *EIEC* are not pathogenic; on shifting the growth temperature to 37° C, these enteric organisms become virulent. Inactivation of *virR* by transposon mutagenesis yields constitutive expression of the invasive phenotype at both 30° C and 37° C.

The Shiga toxin genes *stxA* and *stxB* are near 28 minutes on the chromosomal map of *S. dysenteriae* type 1;[91] colony hybridization results indicate that other shigellae, including the other 12 serotypes of *S. dysenteriae*, do not have the structural genes for the Shiga toxin.[73] One plausible explanation why *S. dysenteriae* type 1 produces more severe clinical symptoms than other shigellae may be attributed to the action of the Shiga toxin. However, the role of the Shiga toxin in *Shigella* pathogenesis is not clear because mutants of *S. dysenteriae* type 1 lacking this toxin elicit clinical manifestations of the disease including dysentery.[25]

Shiga toxin (Stx) is a heat-labile exotoxin. The site of action of this toxin is on the vascular system of the central nervous system but it does not directly affect neurons. The toxin does inhibit protein synthesis in the host target cell. Shiga and Shiga-like toxins of *E. coli* have common properties:

1. they share sequence homology (the Shiga toxin and Stx1 from *E. coli* O157:H7 are nearly identical)
2. they have similar modes of action
3. they bind to eukaryotic cell membrane receptors with a specific galactose moiety
4. they possess the same stoichiometry of one A to five B subunits.

Shigella species also synthesize two enterotoxins—ShET1 and ShET2. The genes for *Shigella enterotoxin* 1 (*set1A*, *set1B*) are a chromosomally encoded operon and are iron-regulated. Enterotoxin ShET1 is present predominantly in *S. flexneri* 2a strains, is rarely found in other *Shigella* isolates, and is lacking in *EIEC* strains.[74] The other enterotoxin, ShET2, is plasmid-encoded and is present in *EIEC* and more than 80% of *Shigella* serotypes tested.[71] These toxins may be involved in the production of watery diarrhea in the infected host.

The virulence genes of *Shigella* are summarized in Table 46–3.

Table 46–3 *Shigella* Virulence Genes

Locus	*Function*
Chromosomal encoded	
stx	Shiga toxin
set1	Enterotoxin
virR/hns	Repressor
rfa, rfb	O-antigen biosynthesis
iuc	Aerobactin, iron acquisition
sodB	Superoxide dismutase
Plasmid encoded	
ipa	Invasion, host-pathogen interaction
mxi/spa	Secretory pathway
ipg	Chaperone
ics	Intracellular spread, actin polymerization
virF	Transcriptional regulator
virB	Transcriptional regulator
set2	Enterotoxin

46.4.3 Plasmidborne Genes

The large virulence plasmid (180 to 220 kbp) is harbored in all four pathogenic *Shigella* spp. and in *EIEC*. These plasmids share extensive DNA homology and functionally are interchangeable. Most of the plasmidborne virulence genes are in two operons oriented in opposite directions (Figure 46–1). Strains lacking this plasmid, or isolates that have deletions in the 31 kbp virulence region, are avirulent. These organisms cannot invade cultured cells or bind Congo Red in an agar medium. In *S. sonnei*, loss of the virulence plasmid not only makes the organism avirulent but also causes a change in colony morphology from Form I to Form II (smooth to rough colonies) due to loss of the LPS.[53]

The immunodominant antigens present in the outer membrane of pathogenic shigellae are the products of the four *ipa* (*invasion plasmid antigen*) genes, *ipaBCDA*. The Ipa proteins are secreted and are essential for invading colonic epithelial cells.[67,119] Extracellularly, IpaB, IpaC, and IpaA form complexes;[68] in the bacterial cytoplasm, IpaB and IpaC appear to react with the *ipgC* (*invasion plasmid gene*) gene product. The proposed role of IpaB is as a contact hemolysin, responsible for lysing the phagocytic vacuoles of the host cell[37] and inducing apoptosis in macrophages.[127] IpaD is thought to be involved in regulating Ipa protein secretion on contact with epithelial cells.[67] The *ipgC* gene, located immediately upstream of *ipaB*, encodes a protein that acts as a chaperone for IpaB and IpaC. In *Salmonella typhimurium*, homologs of IpaB and IpaC have been identified and are necessary for this pathogen to invade epithelial cells in culture.[46]

Products of 20 genes from the *mxi* (*membrane expression of invasion plasmid antigens*) and *spa* (*surface presentation of Ipa antigens*) operons are necessary for shigellae to secrete the Ipa proteins into the extracellular environment. The *mxi* and *spa* gene products share sequence homologies with the secretory proteins necessary to export the *Yersinia* outer proteins (Yops) to the cell surface[108,120] and genes responsible for flagellar synthesis in *E. coli*, *Salmo-*

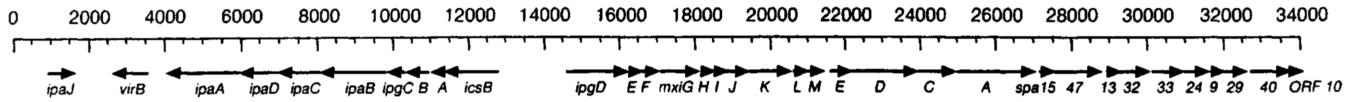

Figure 46–1 Genetic Map of *Shigella* Plasmid Virulence Genes. The map shows the location of genes necessary for *Shigella* pathogenesis on a 31 kbp region on the virulence (180 to 220 kbp) plasmid. The *ipaBCD* (*invasion plasmid antigen*) genes are the immunodominant proteins secreted by *Shigella* spp. The *mxi* (*membrane expression of invasion plasmid antigens*) and the *spa* (*surface presentation of antigens*) genes are part of the protein export system, essential for the presentation of the Ipa proteins on the cell surface. The *virB* gene is a positive transcriptional regulator. Two genes outside this region on the plasmid, *virG* or *icsA* (*intracellular spread*) and *virF*, are not shown.

nella typhimurium, Bacillus subtilis, and *Caulobacter crescentus.*[90,115]

The invasins of Gram-negative bacteria, eg, the ipa proteins of *Shigella* spp., are proteins that do not have any apparent signal peptide sequences and are dependent on a *sec*-independent Type III secretory route to be translocated to the bacterial cell surface or extracellular milieu. The genes of the secretory pathways of *Shigella* and *Salmonella* have similarities in gene order and nucleotide and protein sequence, indicating a possible evolutionary relatedness.[33,39,64] This Type III protein-secretory system also has been found in several distantly related plant pathogens such as *Xanthomonas campestris* and *Pseudomonas solanacerarum.*[23,114]

Three other virulence loci are located outside the 31 kbp region of the large virulence plasmid. The *icsA* (*intercellular spread*) or *virG* gene encodes a 120 kilodalton (kDa) outer membrane protein with adenosine triphosphatase (ATPase) activity. This protein catalyzes the polymerization of host cell F-actin monomers at one pole of the bacterium, producing an actin tail at that end. This activity propels the organism through the cytoplasm of the host cell into adjacent cells. The localization of IcsA on the outer membrane of *Shigella* appears to be dependent on intact LPS;[86] however, when the *icsA* gene alone was transferred to *E. coli*, the formation of actin tails still was observed. This led to the conclusion that the *icsA* gene may be solely responsible for intercellular movement.[31] Recently, another gene, *virA*, located upstream of *icsA*, was identified as a factor affecting invasion and intercellular spread.[113] The *virF* gene product is a positive regulatory protein and its role in *Shigella* pathogenesis is discussed below.

46.4.4 Regulation

The coordinate regulation of the virulence genes of this pathogen involves a complex cascade of molecular and physiological events. The molecular mechanisms by which *Shigella* spp. respond to environmental conditions, such as temperature and pH, have not been fully determined. *Shigella* spp. use positive and negative transcription factors to control the expression of unlinked genetic loci.

Temperature plays a critical role in regulating the expression of virulence factors of shigellae and *EIEC*. At 30° C, *Shigella* and *EIEC* are noninvasive phenotypically, but after growth at 37° C, these cells become fully pathogenic. Temperature regulation is mediated by *virR*, encoding a histone-like repressor protein (H-NS). H-NS acts by repressing the expression of the plasmidborne *virB* gene. The VirB protein, a transcriptional activator, positively regulates the expression of the *ipa*, *mxi*, and *spa* genes. The transcription of the *virB* gene is stimulated by the *virF* gene product, which binds to a region upstream of *virB*. The *virF* gene product also regulates positively the expression of the *icsA* gene at the transcriptional level. *VirF* expression apparently is not dependent on the growth temperature, although the function or conformation of the VirF protein may be affected by temperature. In a recent report, the expression of *virF* was shown to be dependent on the pH of the extracellular environment through the involvement of the *cpxA* gene.[70]

46.5 INCIDENCE OF THE ORGANISM IN THE ENVIRONMENT AND IN FOODS

S. dysenteriae was the major cause of bacillary dysentery at the beginning of the 20th century. Episodes of shigellosis caused by this pathogen decreased dramatically after World War I. *S. flexneri* then became the leading cause of shigellosis worldwide and has remained so in developing countries. After World War II, *S. sonnei* was the most frequent isolate recovered from patients in developed countries. *S. sonnei* remains the leading *Shigella* spp. isolated from humans with shigellosis in the US. In 1969, *S. dysenteriae* reappeared in Guatemala; this pathogen has become endemic in Africa and Asia. Considerable numbers of shigellosis outbreaks caused by *S. boydii* are found in India (see Table 46–2).

The primary route of transmission of *Shigella* spp. is the fecal-oral route. In developing countries, the spread of these pathogens is sometimes rapid due to contamination of local water supplies. In developed countries where proper sanitation exists, the dissemination of shigellae remains a public concern. Poor personal hygiene of food handlers, whether in large institutions or in small hometown cookouts, contributes significantly to several outbreaks each year. Outbreaks in day-care centers and nursing homes have become very common. In the former, toddlers have not developed good toilet training habits and easily can spread the pathogen to other children or adult supervisors.

46.6 EPIDEMIOLOGY

46.6.1 Incidence of Outbreaks and Sporadic Cases

There are three major routes for contracting shigellosis: person-to-person contact, ingestion of contaminated water, and ingestion of contaminated food. Person-to-person spread of the organism is the most common route for the spread of shigellae. This pathogen can be disseminated from infected individuals by flies, fingers, food, or feces.[32] Houseflies are considered passive vectors and can be responsible for epidemic dysentery. Shigellae are capable of passing through the gut of flies and can be transported directly by flies to foods from contaminated feces. Shigellosis outbreaks are seasonal; higher incidence occurs during warmer periods of the year. Because the infectious dose of shigellae is very low, the likelihood of developing clinical shigellosis and rapid dissemination of this pathogen within a given population is high.

A major cause of small- or large-scale foodborne outbreaks is poor personal hygiene of a food handler. Cool, moist foods that require extensive handling after the ingredients are cooked, such as egg or potato salads, are good vectors for spreading shigellae from infected food handlers to unsuspecting consumers. The second-leading cause of foodborne outbreaks of shigellosis is the improper storage of contaminated foods;[102] contact with contaminated equipment, inadequate cooking, and unsafe food sources are other contributing factors.

A decrease in US foodborne outbreaks of shigellosis has been reported to the Centers for Disease Control and Prevention from 1983 to 1992. In 1983–1988, there were 110 foodborne outbreaks of shigellosis with 17,990 cases; whereas in 1992, only 1 outbreak and 4 cases were reported. The World Health Organization (WHO) tracks foodborne outbreaks caused by a number of bacteria, including *Shigella* spp. in Europe and several Asian countries.[124] In the years 1985–1989, Hungary reported 7 shigellosis outbreaks, Romania had 2 outbreaks with 73 cases, the former Yugoslavia counted 6 outbreaks, and Spain 13 outbreaks. In Israel, 25% of all foodborne outbreaks were caused by shigellae. Twenty-seven outbreaks with 11,098 cases were reported during this period.

Members of the genus *Shigella* have a limited host range, which is restricted mainly to humans and higher primates, including gorillas, gibbons, and macaques. Frequent outbreaks are mostly associated with zoological (conservation) parks and primate research centers with *S. flexneri* as the primary causative agent, and *S. sonnei* infrequently isolated.[5,60,106] In some instances, animal caretakers have contracted shigellosis by tending monkeys shedding shigellae.[50]

Examples of Foodborne Shigellosis Outbreaks

The following outbreaks of shigellosis indicate that the spread of *Shigella* from contaminated foods to unsuspecting individuals can occur under many different circumstances.

1994: Shigellosis in Europe. An outbreak of shigellosis occurred in Norway, the United Kingdom, and Sweden. The probable cause was the ingestion of fecal-contaminated iceberg lettuce imported from Spain. Although *S. sonnei* was not recovered from this food, a well-documented case-control study implicated imported lettuce. The coliform count found in lettuce samples was up to 10^8 cfu g^{-1} indicating fecal contamination, most likely due to irrigation practices using poorly treated sewage water.[47]

1992-1993: Operation Restore Hope in Somalia. Diarrheal diseases were experienced among US troops stationed in Somalia participating in Operation Restore Hope. The leading cause of diarrhea among personnel was *Shigella* spp. (33%), followed by enterotoxigenic *E. coli* (16%) and *Giardia lamblia* (4%). *S. sonnei* was linked to 10 cases that involved a common eating facility.[95]

1992: Shigellosis outbreak at a central commissary in Michigan. A review of the premises at a commissary in Michigan revealed that several food handlers were ill before an outbreak of shigellosis that involved 43 individuals. *S. flexneri* was the causative agent, and tossed salads were the suspected food vehicle.[18] This scenario typifies several aspects of infections due to *Shigella*: the relative ease with which *Shigella* can spread through a population, uncooked vegetables as a common vehicle for dissemination of shigellae in foods, and the contribution of food handlers with poor personal hygiene to the transmission of the pathogen. The need for food establishments to monitor food handlers is well recognized as a critical factor to be addressed.

1991: Shigellosis caused by moose soup. At a community festivity in Galena, Alaska, 17 of 19 case patients with gastroenteritis ate homemade moose soup. *S. sonnei* was isolated from 10 of these patients. The soup was prepared in five different homes; in one household, one person complained of having a gastrointestinal problem either before or during the preparation of the soup. Because no other food was implicated in the outbreak, this would indicate that the contaminated moose soup was prepared from one of these households.[29]

1988: Large shigellosis outbreak at a music festival. At an outdoor music festival, approximately 3,175 people reported a diarrheal disease caused by *S. sonnei*. A total of 6,403 people attended this gathering. A week before the festival commenced, gastroenteritis was reported among the 563 staff members. It appears that the transmission of the infective agent to attendees was initiated by ill staff members. Contributing factors to this large outbreak were lack of proper sanitary conditions (lack of adequate soap and handwashing facilities) and the large number of food handlers (2,000 people).[58]

1987: Large shigellosis outbreak at a mass gathering. More than 12,700 people attended a mass gathering where more than 50% of the attendees experienced a diarrheal episode. The mode of transmission was most likely food, water, and person-to-person contact. Sanitary conditions were poor with kitchen facilities located near open latrines. Exacerbating the problem was the fact that food handlers with gastroenteritis were not excluded from food preparation. An antibiotic-resistant (ampicillin, tetracycline, and trimethoprim-sulfamethoxazole) strain of *S. sonnei* was identified as the causative agent.[121]

Examples of Waterborne Shigellosis Outbreaks

1991: Shigellosis in Thailand. Shigella flexneri 2a was responsible for an outbreak of shigellosis in Thailand. This waterborne outbreak was most likely due to a piped public water supply with an interruption in chlorine treatment and subsequent contamination with fecal matter.[109]

1991: Lake contaminated with Shigella. Over a 24-day period at a lakeside park near Portland, Oregon, 59 people had bloody diarrhea caused by either *S. sonnei* or *E. coli* O157:H7; the latter pathogen also was responsible for several people developing HUS. Consumption of food or beverages was not implicated in the spread of the disease. The fecal coliform count in the lake was substantial. *E. coli* O157:H7 isolated from lake water samples were identical to patient isolates as determined by pulse-field gel electrophoresis.[49]

1990-1991: Outbreak of shigellosis on the Island of Crete. Nearly one-tenth of the 1,479 inhabitants of one village on the Island of Crete had diarrheal disease, with 30% of the children under the age of 12 years being symptomatic. *S. sonnei* was isolated from stool cultures, and the mode of transmission was most likely due to contaminated spring water.[85]

46.7 FACTORS AFFECTING SURVIVAL AND GROWTH IN FOODS

Shigella, unlike other foodborne pathogens such as *Salmonella* and *Listeria*, are not indigenous to one particular food. The addition of *Shigella* to foods is usually the consequence of a food handler with poor personal hygiene; however, raw vegetables and fruits can be tainted with contaminated water either used for irrigation or washing. Examples of foods that have been implicated in outbreaks are potato salad, tossed salads, spaghetti, egg salads, white cheese, tuna salad, stewed apples, chicken, shrimp, clams, and milk.[102]

Studies on the survival and growth of shigellae in foods have focused mostly on *S. sonnei* and *S. flexneri*, with some work reported with *S. dysenteriae*. Much of this information has been reviewed by the International Commission on Microbiological Specification for Foods,[42] and some of those data are presented below.

The ability of shigellae to survive in foods can depend on a number of factors. The temperature at which the food is held, the pH, and presence of inorganic acids in foods have a critical part in the survival of this pathogen.

Shigellae can survive over a range of temperatures. *S. sonnei* can grow in nutrient broth at temperatures as low as 6° C (*S. flexneri* as low as 7° C). In foods, *S. flexneri* and *S. sonnei* can survive when stored at –20° C, 4° C, and room temperature when exposed to 80° C for a few seconds. The length of survival is quite different for each temperature, with shigellae surviving for the longest period at room temperature.

The chances of recovering shigellae from foods seem to be better in foods with neutral pH—eg, margarine and butter—because these bacteria survive for long periods (greater than 120 days) even at temperatures at –20° C and 4° C. In acidic foods, such as citric juices and carbonated soft drinks, *S. flexneri* and *S. sonnei* can survive from 4 h to 10 days. *S. dysenteriae* was tested for survival in orange and grape juices at –4° C and 20° C, respectively, and was found to survive from 2 to 28 hours in grape juices and up to 170 hours in orange juice. *S. sonnei* did grow in media with pH values between 4.8 and 9.3, and *S. flexneri* had nearly the same pH range, from 5 to 9.2.

In foods that have been implicated commonly in shigellosis outbreaks, such as cheese, potato salad, and mayonnaise, *S. sonnei* and *S. flexneri* can survive at 4° C for 21 days. In Greek cheese, *S. sonnei* can survive from 24 to 92 days depending on the storage temperature; at 4° C, this bacterium survived the longest.

The presence of organic compounds, such as formic or acetic acid and salts, eg, NaCl, has a pronounced affect on survival of shigellae in different conditions. No growth was observed in media containing 3.8% to 5.2% NaCl with a pH of 4.8 to 5.0. In media with nitrite concentrations of 300 to 700 ppm at a pH of 5.5, these bacteria did not grow. Overall, *S. flexneri* is more sensitive to inhibitors than *S. sonnei*. *S. flexneri* was less able to grow in the presence of nitrites, salt, and pH at lower temperatures.

In one report,[83] *S. flexneri* survival was tested in several vegetables, either sterile or nonsterile. In either case, the level (10^5 to 10^6 cfu g^{-1}) remained constant for several days. There have been a few outbreaks of shigellosis caused by the ingestion of contaminated vegetables,[16] indicating that *Shigella* can survive in sufficient numbers to produce clinical symptoms. The ability of *Shigella* spp. to survive acid conditions in foods has been sparsely investigated. Two reports[7,104] demonstrated that the number of *Shigella* inoculated into meats was reduced after treatment with formic or lactic acid.

Acid resistance by shigellae appears to be mediated by the *rpoS* (*katF*) gene, a locus encoding for an RNA polymerase sigma factor.[99] A model of gastric acid resistance suggests that this sigma factor controls the expression of genes under duress, such as poor growth conditions (eg, low temperature, depleted nutrient supply); thus, the genetic factors for acid resistance are expressed along with a battery of other survival characteristics.

46.8 PRINCIPLES OF DETECTION AND ISOLATION FROM FOODS

46.8.1 General Comments

Shigella spp. in foods are a potentially serious problem to the public health. Rapid detection of contaminated foods is critical because of the low infectious dose and the potential for rapid dissemination of these pathogens. Contamination of foods usually occurs through a food handler with poor personal hygiene.[102]

Analytical epidemiological studies are often the only way to determine the vehicle of transmission in outbreaks of disease when perishable commodities are involved. Furthermore, most outbreaks of shigellosis are recognized days or weeks after exposure or onset of the disease. Analysis of suspected foods may be further compromised by improper storage conditions (abused by temperature or time) or loss of the food sample (disposed or eaten).

In foodborne outbreaks caused by *Shigella* spp., the initial recognition of shigellosis usually is based on the results from examining patient samples in the clinical laboratory. Detection of *Shigella* in this milieu is enhanced by two significant factors: humans are efficient incubators for this pathogen and can shed considerable numbers of *Shigella* in stools, and there is usually only one type of clinical sample to be analyzed, ie, stool specimens. Therefore, clinical identification schemes based on standard bacteriological means are fairly straightforward. This luxury is not present for the food analyst.

Foods vary greatly in composition (pH, fat, and oil content) and the indigenous microbial flora. The food analyst must consider these factors to implement the correct scheme for detecting shigellae in foods. An accurate diagnosis of the presence of shigellae in foods usually is inconclusive because of the low numbers or injured state of the *Shigella* spp. present and further complicated by the composition and consistency of the food sample.

The variability of the indigenous microbial load of each food poses a significant problem for detecting *Shigella* in foods whether by bacteriological methods or by DNA-based assay systems. For instance, some foods, such as alfalfa sprouts, have a microbial flora of 10^7 to 10^8 cfu g^{-1},[55] and the indigenous population can easily outcompete and therefore outgrow any *Shigella* spp. present. The problem of having a high bacterial population and a low number of *Shigella* can affect the successful recovery of *Shigella* spp. from foods. Because of its low infectious dose, *Shigella*, even in undetected levels in foods, still poses a significant public health risk.

Detecting or recovering shigellae in foods is a daunting task with a low probability of success. Smith[102] has commented on the resuscitation of injured (or abused) shigellae from foods and the low chance of recovery. Implementing DNA-based techniques may increase the chance of detecting shigellae in foods but, to date, these methods have not been tested rigorously in foods.

The use of probes for the detection of shigellae may be limited. In many foods, the microbial flora are present in higher numbers than the shigellae; therefore the *Shigella* spp. present would not be represented on the agar plates after diluting the samples to yield an appropriate number of cfus per plate. The polymerase chain reaction (PCR) may be a preferred detection method rather than using hybridization protocols with gene probes. The number of target cells for PCR is between 10^2 and 10^3 whereas for probes 10^3 to 10^5 cfu g^{-1} is needed. The major hindrance for PCR detection is the preparation of template DNA; inhibitors of the PCR from the food sample must be removed and enough template must be available to be amplified in sufficient quantity.

46.8.2 Standard Bacteriological Methods

Conventional bacteriological methods for the recovery and identification of *Shigella* spp. from foods can take 7 to 10 days. Suspected food samples are grown initially in enrichment broth followed by biochemical tests for preliminary identification and subsequent serological assays for confirmation. The *Bacteriological Analytical Manual*[2] details how some government agencies and food companies analyze food samples. An enrichment step includes adding a portion of the food to Shigella broth supplemented with 0.5 to 3 $\mu g\ ml^{-1}$ of novobiocin. This antibiotic appears to inhibit many Gram-negative bacteria but does not affect the growth of *Shigella*. The broth culture is grown anaerobically at 42° C to 44° C for 20 hours and then streaked onto MacConkey agar plates. After growth at 35° C for 20 hours, suspected lactose-negative colonies are examined by Gram-stain and tested for specific biochemical reactions (eg, H_2S, urease, lysine decarboxylase, citrate) and subsequently tested by group-specific antiserum. Shigellae are thought to be nonmotile, and motility agar is used as a diagnostic indicator; however, one report suggests that *Shigella* spp. may be minimally motile.[30] Therefore, this test may be unsatisfactory for identifying all *Shigella*.

Different bacteriological methods also are available for identification of *Shigella* spp. Food samples also can be grown in enrichment broth cultures of Gram-negative or selenite cystine broth.[4] Overnight cultures can be plated onto several different selective media including MacConkey, *Shigella-Salmonella*, xylose-lysine-deoxycholate, eosin-methylene blue, or deoxycholate citrate agar plates. Another scheme uses growth on either triple-sugar iron or Kligler iron agar slants, and suspected cultures are again identified using biochemical and serological criteria.

The enumeration and identification of foodborne microbes using standard microbiological regimens is labor intensive, time consuming, and lacks the specificity and sensitivity needed to detect these pathogens in foods.[2] With the techniques of immunobiology and molecular genetics, alternative methods such as DNA probes, PCR, and monoclonal antibodies can be applied to the development of detection assays for foodborne pathogens.

46.8.3 Genetic and Immunological Methods

46.8.3.1 DNA-Based Assays

The first gene probes developed to detect *Shigella* targeted these pathogens in clinical samples.[10,100,111,123] DNA fragments were isolated from the large virulence plasmid resident in pathogenic strains of *Shigella* and used in a colony hybridization format to discriminate between virulent (retaining the virulence plasmid) and avirulent (cured of the virulence plasmid) strains. Table 46–4 summarizes the DNA probes used to target specific regions of the large virulence plasmid.

In one study, a specific oligonucleotide was synthesized based on the sequence of the repeated *ipaH* genes and used as a probe to detect *Shigella* spp. and *EIEC* isolated from clinical samples.[116,117] Copies of the *ipaH* genes are located on the *Shigella* chromosome and on the large virulence plasmid, which makes this oligonucleotide a useful genus identification probe. A comparison was made using an alkaline phosphatase-conjugated oligonucleotide probe for the *ipaH* gene and the Séreny test in identifying virulent strains of *Shigella* spp. These comparisons were made using cultures isolated from clinical

Table 46–4 DNA Probes and PCR Primer Sets for Detecting *Shigella*

DNA Probes

Probe	*Type*	*Application*	*Reference Number*
17 kbp	Plasmid DNA	Clinical	21,111
2.5 kbp	Plasmid DNA	Clinical	93,100,123

ial	Oligonucleotide	Clinical	63
ial	Oligonucleotide	Food	45

PCR Primer Sets

Target	*Application*	*Reference Number*
ial	Clinical	26
ial	Food	56
ipa	Clinical	117
virF	Clinical	125
uidA	Clinical	6,14
phoE	Clinical	105

samples;[117] however, avirulent strains (plasmid-less) of *Shigella* and *EIEC* also can be detected with this probe.

In contrast, for food analysis, a synthetic 18-base long oligonucleotide, based on the nucleotide sequence of a virulence gene found in a 2.5 kbp HindIII fragment from the invasion plasmid[90,100,111] was used as a probe. Although several genes have been identified in this 2.5 kbp fragment, this oligonucleotide probe targeted the *ial* (*invasion associated locus*)[101] also known as ORF8.[90] The oligonucleotide probe was tested for specificity, with *Shigella* and *EIEC*, and sensitivity, in several foods seeded with *S. flexneri*.[45] The efficacy of this probe was dependent on the seeded food. *S. flexneri* seeded (10^2 cfu g^{-1}) in alfalfa sprouts could not be detected by colony hybridization; the microbial background (1.4×10^8 cfu g^{-1}) of this particular food apparently outgrew the seeded *Shigella*.

DNA probes for the detection of pathogenic *Shigella* and *EIEC* in foods using the colony hybridization blot format suffer other disadvantages. In cases where food samples are time or temperature abused, an enrichment step in broth cultures may not resuscitate the requisite number of cells to detect by hybridization. The low infectious dose of *Shigella* means that contaminated foods may fall below this level of detection, ie, give a false negative result. Also, analyzing foods with DNA probes, as with other bacterial cultural methods, is time consuming and laborious. The application of PCR has overcome some of the disadvantages of DNA probe and culture methods and has reshaped the direction for developing methods for the detection of *Shigella* spp. and *EIEC*, not only in the clinical laboratories but also in food analysis.

Several PCR primer sets directed against known virulence markers, such as the *ial* locus (ORF8),[26,56,62] the *ipaH* gene,[94,117] and the *virF* locus[125] and genes not associated with pathogenesis, eg, *uidA*, *phoE*, have been tested in a PCR assay.[6,14] Most of these PCR assays were tested with clinical or water samples. Table 46–4 summarizes PCR primers used to detect *Shigella* in either clinical or food samples.

Another method combines PCR with immunomagnetic separation to detect *S. dysenteriae* type 1 and *S. flexneri* from feces.[43] The monoclonal antibodies used in this assay target a common epitope of the O-polysaccharide of both pathogens and were used to coat magnetic beads. Bacteria that bind to the beads directly from stool samples are used as templates in a PCR assay specific for these *Shigella* species using *ial*-specific PCR primers. The reported sensitivity of a combined immunomagnetic separation, PCR, and dot blot hybridization was 10 to 15 shigellas g^{-1} of fecal sample.

For epidemiological analysis, molecular typing methods have been compared to determine the best technique to type *S. sonnei* isolates. Plasmid profile, restriction endonuclease digestions of plasmids, rRNA gene restriction (ribotyping), pulsed-field gel electrophoresis, and enterobacterial repetitive intergenic consensus (ERIC) sequence-based PCR analysis were used; the last showed the most promise for typing *S. sonnei*.[61]

Clinical samples are rather consistent in composition and the number of *Shigella* cells shed in positive stool specimens can be high. The physical composition of each food, eg, fats, oils, may have an adverse affect on the PCR chemistry. Therefore, unlike the clinical sample, each food matrix may pose a unique challenge in extracting a suitable number of target DNA molecules from *Shigella*.

PCR has been used to analyze food samples that were seeded with either *S. flexneri*[56,83] or *EIEC*.[1] PCR primers were selected to target the *ial* gene (ORF8). PCR products of the appropriate size, as visualized by gel electrophoresis, were amplified from seeded foods. With improved DNA isolation techniques and faster thermocyclers, it is possible to detect *Shigella* in foods in less than 8 h. PCR-based assays are rapid and sensitive and do not require selective enrichment or high cell numbers.

PCR-based assays do have their disadvantages. As in any PCR system, template DNA from live and dead cells can yield positive results. But in the case of *Shigella*, these bacteria are not indigenous to any food and it can be argued that a positive result from PCR indicates contamination with human fecal matter. A limitation of a PCR assay that targets a plasmid-encoded virulence factor for detecting *Shigella* in foods is that the loss of the virulence plasmid renders PCR (and probe) methods ineffective. With *S. sonnei*, this is a problem because these pathogens lose the virulence plasmid quite readily during isolation and storage.[65,88] PCR primers for the *ipaH* gene can overcome the problem of plasmid loss because this genetic marker is also on the chromosome. However, because plasmid-less strains are avirulent, targeting the *ipaH* gene may not satisfy regulatory concerns of governmental agencies.

The incidence of antibiotic-resistant shigellae is increasing worldwide and is a great concern to the medical community in treating outbreaks. To increase the chance of recovery and detection of *Shigella* in foods by genetic-based assays, antibiotics can be incorporated into enrichment medium or in agar plates. This effectively reduces the microbial flora of the food sample and maintains selective pressure on the *Shigella* spp. for that particular antibiotic. Because most shigellosis outbreaks are identified initially in the clinical laboratory, the choice of antibiotic to use is dependent on the antibiotic resistance profile of the isolated pathogen. This information can be most useful to the food analyst in identifying the source of the foodborne outbreak. This method has proven effective with foods, such as alfalfa sprouts and ground beef, that have high background flora [A.-A. Molina and K.A. Lampel, unpublished observation].

46.8.3.2 Latex Particle Agglutination Assays

For clinical samples, several commercial latex agglutination tests are available for the detection of *Shigella* spp. A color-coded latex kit (Wellcolex Color Shigella Test; Wellcome Diagnostic Research, Triangle Park, NJ) and the Bactigen Salmonella-Shigella Latex Agglutination Slide Test (Wampole Laboratories, Cranbury, NJ) were tested for specificity and sensitivity using enrichment broth cultures of clinical samples and direct culture identification.[17,69] The specificity of both latex agglutination methods ranged from 93.6% to 99.2%, although it should be noted that the number of samples used in the slide-test method was quite low. The sensitivity of the color-coded latex kit was 97.1%; with pure cultures, 98%.[11]

A hydrophobic latex particle agglutination assay that can differentiate virulent, plasmid-bearing *Shigella* spp. from avirulent, plasmid-less strains has been reported.[9] Although this method is rapid, its efficacy in detecting *Shigella* in food samples has not been determined.

46.8.3.3 Other Antibody-Based Assays

Enzyme-linked immunosorbent assay (ELISA). One ELISA test uses antibodies raised against an *EIEC* "virulence marker antigen" and was shown to identify clinical isolates of *Shigella* and *EIEC.*[77] This application, although it could screen a large number of clinical isolates in 24 hours, was tested using pure isolates and has not been applied to detecting *Shigella* from foods.

Immunomagnetic. An immunomagnetic assay using monoclonal antibodies directed against the O-antigens of *S. dysenteriae* type 1 and *S. flexneri* was tested using clinical samples and pure cultures.[44] The sensitivity of this assay was shown to be 10^3 cfu ml^{-1} with a specificity of 100%; the assay could detect *Shigella* in stool specimens up to 2 days after antibiotic therapy was initiated in patients.

46.9 CONTROL

Control of shigellosis is best achieved by preventing food and water from becoming contaminated with the microbes. Many food inspection systems have relied on good hygienic practices in food manufacturing and preparation facilities and used endproduct sampling to monitor food safety. This approach to food safety is being replaced worldwide by the Hazard Analysis Critical Control Point (HACCP) approach,[41] a process control system based on identification of points at which biological, chemical, and physical hazards may be introduced into a food. The HACCP approach is addressed in Chapter 58 and will not be discussed in detail here. It is, however, a much more scientifically based approach to ensuring food safety when compared to endproduct sampling. This is especially true when dealing with microbes with low infectious doses such as members of the genus *Shigella*.

The prevention of shigellosis can be enhanced by the application of better personal hygiene among food handlers and consumers. This includes handwashing and, in many countries, improvement in water treatment and better monitoring of food handlers, day-care personnel, and children. Industries employing food handlers and day-care center personnel should have testing of stool samples from infected individuals until negative results are obtained. This policy is in effect in many local jurisdictions in the US.

The use of antibiotic therapy should be dictated by the severity and stage of the disease. In some cases, such as with *S. sonnei*, the disease is self-limited and antibiotic treatment may be unnecessary. However, in more severe cases with bloody diarrhea, dispensing of antibiotic to the patient may reduce the length of the illness. Antibiotics recommended include trimethoprim/sulfamethoxazole, ampicillin, and, in situations with drug-resistant strains, nalidixic acid or 4-fluoroquinolones. A concern of many scientists is that multiple-resistant strains are evolving globally and indiscriminate use of antibiotics may contribute to the spread of antibiotic resistance genes in the bacterial world; therefore, therapy should always follow antibiotic sensitivity testing.

Resistance to antimicrobials can occur quickly, as in the case of *S. dysenteriae*, and has been observed even during a single epidemic. In developing countries, this can be a major obstacle for treatment; antibiotics available locally may no longer be effective, and more expensive alternative antibiotics, which are not on hand, may be needed. Bacterial extrachromosomal plasmids carrying genetic determinants are responsible for dissemination of resistance but the mechanisms for the rapid spread of antibiotic resistance observed with *S. dysenteriae* are not completely known.

The rising incidence of shigellosis outbreaks and the number of antibiotic-resistant *Shigella* encountered continue to be worldwide concerns. The latter problem is not restricted to *Shigella* but is present in a vast number of important human pathogens. As suggested by Høiby et al.,[38] the spread of shigellae via foods and their possible exposure to and selection by antibiotic regimens in clinical environs may add to the antibiotic resistance repertoire of these pathogens. Subsequent dissemination of these strains to other individuals will only increase the persistence of *Shigella* spp. in the world. The WHO has recognized the importance of antibiotic resistance by pathogens such as shigellae. This organization has established a monitoring program to track resistance on a national and regional basis and also to provide guidelines for a rational approach to the use of antibiotics.

No vaccine currently is available; however, there have been several reports recently published on the progress of developing a vaccine for all *Shigella* spp.[81] The WHO specifically has targeted this pathogen for a program leading to a successful vaccine and has supported research for elucidating the molecular and cellular events of *Shigella* pathogenesis.

46.10 CONCLUDING REMARKS

Diarrheal diseases are a leading cause of death of children worldwide. As one of the major diarrheal diseases, shigellosis remains a concern, occurring frequently in developed and developing countries. Improved sanitary conditions and education in better hygiene practices are important factors in reducing the number of incidences of bacillary dysentery. Also, as recognized by the WHO, research to develop a vaccine against *Shigella* spp. and to unravel the genetics of the molecular and physiological mechanisms of host-pathogen interactions can contain the spread of shigellosis. The fact that shigellae have shown a rapid increase in antibiotic resistance makes all these preventive measures increasingly important to those areas in the world where diarrheal diseases lead to high mortality.

Finally, it is incumbent on food microbiologists, the food industry, and the food regulatory agencies to ensure a safe food supply for the consumer. This applies to developing and industrialized nations. Improved methods for the rapid detection of shigellae in foods may facilitate the prevention of the spread of this pathogen.

47.1 INTRODUCTION

The name staphylococcus, derived from the Greek nouns *staphyle* meaning a bunch of grapes and *coccus* meaning a grain or berry, was first used in 1882 by Sir Alexander Ogston to describe the cluster-forming cocci he observed in pyogenic abscesses in man.[115] Two years later, Rosenbach reported the isolation of this organism in pure culture and introduced the name *Staphylococcus aureus* for the orange colony-forming cocci.[128] Over the next 75 years staphylococci were placed by microbial taxonomists in a variety of tribes and families, including the Coccaceae, Metacoccaceae, Streptococcaceae, Micrococceae, and the Micrococcaceae. *Staphylococcus aureus* also was given a number of other specific epithets including *Staphylococcus pyogenes* var. *aureus*, *Micrococcus pyogenes*, and *Micrococcus aureus*.[10,88] *Staphylococcus aureus* is currently the type species of the genus *Staphylococcus*.[30] The genus *Staphylococcus* is a well-defined group of microorganisms that, with the exception of morphology, shares few characteristics with the genus *Micrococcus*. This latter genus has been recently renamed *Kocuria* and is most closely related to the arthrobacters, whereas the genus *Staphylococcus* is most closely related to the genera *Planococcus*, *Enterococcus*, and *Bacillus*.[88]

Although one of the first recorded likely associations of staphylococci and foodborne illness was in 1884 and involved an outbreak of food poisoning associated with cheese,[28] it was not until 1914 that Barber showed that *S. aureus* caused illness by consuming milk from a cow with staphylococcal mastitis.[17] The involvement of a toxin later was shown by Dack and his colleagues, who, in 1930, reported that feeding sterile filtrates of a culture of *S. aureus* to human volunteers resulted in typical symptoms of staphylococcal food poisoning.[46] Since the 1950s, *S. aureus* has been shown to produce a number of antigenically distinct enterotoxins. Up to 1996, 10 were recognized.[171]

47.2 TAXONOMY AND TYPING

47.2.1 Taxonomy

Staphylococci are nonmotile, Gram-positive, and catalase-positive cocci dividing in more than one plane to form irregular three-dimensional clusters of cells. They are facultative anaerobes and use glucose by glycolysis and use of the hexose monophosphate pathway.[88] The separation of staphylococci from micrococci on the basis of their chemical and biochemical characteristics is shown in Table 47–1.

Staphylococcus aureus can be separated from other species of staphylococci by a series of biochemical and resistance characteristics. Table 47–2 shows the principal characteristics separating the main species of staphylococci. For a description of the characteristics of all 31 species recognized in 1992 see Kloos et al.[88]

Staphylococcus aureus usually ferments mannitol and, in the presence of air, uses a wide range of hexoses, pentoses, and sugar alcohols; lactic acid and acetoin are the main end products of glucose metabolism. Other enzymatic activities typical of *S. aureus*, and some closely related species, include: coagulation of animal plasmas by staphylocoagulases and the clumping factor; production of alkaline phosphatase and heat-resistant nuclease (TNase); and production of staphylokinase (fibrinolysin) and a large variety of cytotoxins and cytolysins.[6,88] Staphylococcal enterotoxins are produced mainly by *S. aureus* strains isolated from man (see Section 47.6).

The cell wall of *S. aureus* contains three main components:

1. A peptidoglycan comprising repeating units of N-acetylglucosamine beta-1,4 linked to N-acetylmuramic acid, with the carboxyl group of the muramic acid substituted by an oligopeptide with adjacent units of the peptide bridged by a pentapeptide containing solely or mainly glycine to form a three dimensional structure[131,152]
2. A ribitol teichoic acid bound via (glycerol-phosphate) N-acetylmannosaminyl-beta-1,4-N-acetylglucosamine to a muramyl-6-phosphate residue and composed of N-acetyl-D-glucosaminyl-D-ribitol phosphate in which the N-acetyl group is either 4-O-alpha or -beta linked[89]—the latter corresponds to the group-specific Polysaccharide A[114]
3. Protein A, which is covalently linked to the peptidoglycan and particularly is characterized by its ability to bind with the Fc component of the immunoglobulin of many mammalian plasmas causing autoagglutination.[107]

47.2.2 Typing

The classic method of distinguishing strains of *S. aureus* is to use their relative susceptibility to infection and lysis by different staphylophages, ie, by phage typing. While the pattern of lysis by phages has little or no epidemiological significance, the pattern of lysis to a range of phages is a useful means of distinguishing strains from a particular environment or identifying the possible source of a particular type.[162] There is an internationally agreed basic set of phages used for typing strains of *S. aureus* of human origin, which is updated regularly to reflect changes in the typability of human clinical isolates. Phages additional to the basic set may be used for particular purposes, such as the separation of strains from particular environments. Strains isolated from animals

are mainly untypable by the use of phages used for typing human strains, so other sets of phages are used for typing strains from food animals.[47,104,106] A number of workers have recognized the limitation of phage typing schemes. There are problems of nontypability (15% to 20% of isolates may be untypable) and variation in typability caused by lysogeny and the often poor typability of strains endemic in hospitals.

Antigenic typing, while used by some, has not gained wide acceptance because of antigenic complexity, variability, and the difficulty in preparing specific antisera.[11] However, the combination of antigenic and phage typing is useful in epidemiological and other studies.[43,51]

A variety of molecular probe-based methods have been proposed for typing *S. aureus*, including plasmid profile typing[132] and ribotyping.[32,53] Pulsed-field gel electrophoresis (PFGE) combined with plasmid profile typing was found to be particularly useful for typing *S. aureus* isolates from foods;[156] however, these methods are not widely used at present and it remains to be seen whether any of them will replace phage typing as a routine typing technique. They cannot, at present, compete with phage typing on either cost or throughput rate, although, ultimately, genotyping is likely to be the preferred method for typing strains of *S. aureus*.

A number of attempts have been made to group *S. aureus* strains according to their biochemical and physiological characteristics. Among the most developed of these is that proposed by Hajek and Marsalek.[73] They were able to group *S. aureus* strains from different animal species into six biotypes, using a range of characteristics that included staphylokinase, beta hemolysin, bovine plasma coagulation, and growth on crystal violet agar. This classification has been subjected to a number of modifications as a result of additional studies by other workers, and seven biotypes (A-G) are listed by Devriese.[49] Two of these biotypes (Hajek and Marsalek's biotypes E and F) are currently classified as *S. intermedius*.[50] Separation of the types of *S. aureus* found on humans and domestic animals is shown in Table 47–3.

47.3 CHARACTERISTICS OF DISEASE

tions in warm-blooded animals. These include skin infections such as ulcers, carbuncles, impetigo, and epidermidis necrosis (scalded skin syndrome); infections of the internal organs such as bacteremia, endocarditis, pericarditis, osteomyelitis, meningitis, and mastitis; and intoxications such as toxic shock syndrome and food poisoning.[27,55]

Staphylococcal food poisoning is caused by staphylococci (principally *S. aureus*) growing in food and forming enterotoxins as a product of their metabolism. The symptoms of poisoning include nausea, vomiting, abdominal cramps, and diarrhea. These first occur between 1 and 8 hours (usually 2 to 4 hours) after consumption of a contaminated food. In severe cases, collapse may occur but recovery usually is rapid (within 2 days) and uneventful.

While staphylococcal food poisoning is almost always caused by *S. aureus*, enterotoxins also may be produced by some strains of *S. intermedius, S. hyicus, and S. chromogenes*;[2,25,64] these and some other coagulase-negative staphylococci may cause typical staphylococcal food poisoning.[29,36,158]

47.4 MECHANISM OF PATHOGENICITY

Staphylococci produce a wide range of toxins and exoenzymes including membrane-damaging toxins (alpha, beta, gamma, and delta toxin and leucocidin), epidermolytic toxin, and enterotoxin.[6] Staphylococcal enterotoxins (SEs) are low molecular weight (26 to 30 kDa), single chain proteins with isoelectric points between 5.7 and 8.6.[29,171] Their molecular composition is characterized by containing only two residues of half cystine and one or two residues of tryptophan; they contain relatively large amounts of lysine, tyrosine, aspartic, and glutamic acid.[29] They are markedly resistant to degradation by proteolyic enzymes and heat (see Section 47.7.1).

Currently, 10 enterotoxins are recognized: SEA, SEB, SEC$_1$, SEC$_2$, SEC$_3$, SED, SEE, SEF, SEG, and SEH.[27,171] Enterotoxins A, D, and E have very similar molecular compositions, as have SEB, SEC$_1$, SEC$_2$, and SEC$_3$; SEF, SEG, and SEH have dissimilar compositions.[29,171]

The locations of the genetic material responsible for control of a number of these enterotoxins have been identified. The genes responsible for the production of SEA, SEB, and SEC are on the chromosome, whereas those of SED are on a plasmid;[29,88] the nucleotide sequences of the genes responsible for the main enterotoxins also have been identified.[31,155] Some enterotoxins, such as SEA and SED, are produced and released by the cell throughout the growth phase, whereas others such as SEB and SEC are typical secondary metabolites and are produced by the cell at the end of the growth phase and the beginning of the stationary phase.[28,29] This difference also is reflected by the amounts of different enterotoxins produced by *S. aureus* growing under optimal conditions in laboratory media. These may exceed 100 µg ml^{-1} for SEB and SEC production, compared with only 1 to 10 µg ml^{-1} for SEA and SED production.[155] More importantly from the point of view of their production in foods is that SEA and SED (the principal toxins involved in staphylococcal food poisoning in man) are produced in foods under a wider range of pH, E_h, and a_w than are the other enterotoxins (see Section 47.7).

Staphylococcal enterotoxins and the closely related toxic shock syndrome toxin are of particular interest to immunobiologists as they are "super antigens" and are able to bind to the major histocompatability complex (MHC) class II antigen, causing massive T cell stimulation with the release of cytokines.[41,70,145] The ability of SEs to bind to MHC class II molecules and cause the release of cytokines has been suggested by some workers to be the mechanism whereby enterotoxins cause the vomiting response typically following the ingestion of these proteins.[70,90] Thus, the release of cytokines may result in stimulation of neuroreceptors in the intestinal tract, and triggering of the vomiting center in the brain. However, this mechanism of action has yet to be proved, and many studies aimed at understanding the mechanism of action of SEs have not provided experimental evidence to support hypotheses of their mode of action.[62]

The amount of toxin necessary to cause illness depends on the sensitivity of the individual. Factors affecting sensitivity include weight and immunological status; animals exposed to enterotoxins rapidly become resistant to the specific enterotoxin fed or injected intraperitoneally, and sensitization to enterotoxin occurs among people exposed to the toxin in the laboratory. In a study in which toxin was fed in varying amounts to human volunteers, an emetic dose (ED_{50}) of 0.2 $\mu g\ kg^{-1}$ was obtained for SEA, SEB, and SEC equivalent to an amount of 10 to 20 μg for an adult. However, there is much evidence, based on the measurement of amounts of SE in foods implicated in food poisoning incidents, that the amount able to cause illness may be much smaller and it is generally accepted that 1 μg of SE can cause food poisoning.[57,127,168] To produce sufficient enterotoxin to cause illness, a producing strain needs to produce a concentration of cells of at least 1 million g^{-1} or ml^{-1}.

47.5 INCIDENCE OF THE ORGANISM IN THE ENVIRONMENT AND IN FOOD

Staphylococcus aureus occurs widely as a commensal on the skin and mucous membranes of warm-blooded animals. Frequency of occurrence on human skin is rather variable but numbers occurring on normal, undamaged, and disease-free skin generally are low. The organism is transient and does not usually become part of the resident flora of the skin. However, under conditions where the balance of the normal microbial flora is disturbed, for instance by the topical application of a broad-spectrum antibiotic or frequent immersion of hands in water resulting in soreness and damage to the skin, *S. aureus* may become established as part of the resident flora and multiply to high numbers. The latter conditions have been known to occur on the hands of nurses in hospitals and operatives in food-processing plants, eg, among those stripping cooked meat from chicken carcasses, and result in extensive carriage of *S. aureus* on the hands. More usually, *S. aureus* is carried in the nares and perineum and will be present in these regions of the body in about 50% of the population. It will be found in similar sites in other animals; nares being a particular source.

Determinations of numbers on the skin of food animals indicate a generally high incidence but, in the absence of disease, only low numbers. For instance, numbers on the skin of healthy poultry are generally <100 g^{-1} but numbers may be several orders of magnitude higher on processed poultry carcasses as a result of contamination by equipment used in the defeathering process.[104] *S. aureus* also occurs only at low numbers (<100 ml^{-1}) in raw bulk milk but numbers may exceed 1 million ml^{-1} in milk from a mastitic cow.[67] Its wide occurrence in humans and food animals is reflected by its common occurrence in low numbers in many foodstuffs. For instance, in raw beef, 16%;[150] pork sausage, 33%;[58] raw chicken, 41% to 84%;[99,104,150] seafood, 38%;[1] and bakery products, 10%.[147]

Staphylococcus aureus survives well in the environment and is commonly found in food factories where it may become part of the flora of processing equipment and act as a source of contamination or recontamination. This is well demonstrated by a number of studies of the establishment of "endemic" strains of *S. aureus* on the equipment in poultry plants.[103,111] These strains may be an important source of contamination of processed poultry and some may show increased resistance to chlorine.[33] *S. aureus* survives well in dust, and may be found in dust from cyclones and ventilation. Its ability to survive well in the environment is a source of many cross-infection problems in hospitals and has been a common cause of infections among machine operators in engineering plants as a result of multiplication in the fluids used for cooling the metal during milling.

47.6 EPIDEMIOLOGY

Staphylococcal food poisoning mainly is caused by human strains of *S. aureus* (principally Hajek and Marselek's Biotype A) producing SEA and/or D, with the majority of strains producing SEA alone.[84,105,160] While reports of the incidence of enterotoxin-producing strains among strains of *S. aureus* isolated from humans and other animal species show wide differences,[49] the incidence of enterotoxin-producers among human isolates generally is reported to be much higher than among nonhuman isolates. Thus, the incidence among human isolates is reported to vary from 60% to 80%,[105,126] which contrasts with incidences of 3% to 50% for strains isolated from animal sources.[49,137]

A further difference between enterotoxin production by strains from human and nonhuman sources is that the latter more frequently produce enterotoxins other than Type A, with SEC and SED being the most commonly occurring types.[49,67,84] For instance, in a study of the incidence of enterotoxin-producers among Hajek and Marsalek's biotypes of *S. aureus*, isolated from man and domestic animals, 75% of

Biotype A strains from humans were SEA, SEB, or SEC producers (as were 28% of the human Biotype A isolated from domestic animals), while only 1.2% of 490 isolates from other animals (all but one belonging to Biotypes B and F) produced these enterotoxins;[72] SEC production is common among coagulase-negative staphylococci producing enterotoxins.[158]

47.6.1 Incidence of Outbreaks and Sporadic Cases

The reported incidence of staphylococcal food poisoning in Western countries generally has decreased numerically over the past 25 years. It was the most frequently reported cause of foodborne illness in the United States (US) in the early 1970s and was responsible for 29% of the reported outbreaks and 39% of the cases;[34] this compared with 9% of outbreaks (6% of cases) reported to be caused by salmonella. This contrasts with an incidence of 2.0% of outbreaks (10% of cases) reported in England and Wales for the same period with the majority of outbreaks (98%) caused by salmonella.[76] A large part of this difference probably reflects the status of the reporting systems in these two countries at that time, and these differences largely have vanished over the past two decades. Thus, the number of outbreaks of staphylococcal food poisoning reported in the US in 1983–1984 was approximately 10% of the total, with the majority of the reported outbreaks and cases caused by salmonella;[154] however, staphylococcal food poisoning remains the main reported cause of food poisoning in a number of countries, eg, Brazil and Egypt.

The incidence of staphylococcal food poisoning reported for 22 European countries for 1990-1992 ranged from approximately 20% to <1% of total outbreaks with an overall figure of 3.5%;[165] the United Kingdom (UK) reported one of the lowest incidences of outbreaks of staphylococcal food poisoning (<2.0% of the total).

The size of most staphylococcal food poisoning incidents is quite small (10 cases or less). The most frequent cause of these incidents is the preparation of cooked food well in advance of consumption, followed by poor handling and storage. Large incidents have involved food preprepared for a party or an outside event and where the food has been handled by an *S. aureus* carrier during preparation, followed by the food being kept at warm ambient temperatures for 4 or more hours prior to consumption. Foods involved have included cooked meats, poultry, seafoods, and cream-filled bakery products.

Although not common, incidents involving manufactured foods do occur and may involve 100 or more ill people. Reported incidents include:

- cheese, in which failure of a starter culture allowed *S. aureus* to grow to high numbers and to produce enterotoxin;[172]
- salamis, in which production conditions were changed—ie, fermentation temperature raised to speed up the manufacturing process—allowed *S. aureus* to grow to sufficient numbers to produce enterotoxin before growth was suppressed by acid production by the fermentation flora;[113,157]
- pasta, in which *S. aureus*-contaminated egg used in a pasta mix grew to high numbers in the mix during the extended blending and drying processes at 30° C to 40° C;[168]
- canned meat, fish, and vegetable products contaminated after the sterilization processes as a result of manually handling warm and wet cans or contact of the seams of such cans with equipment contaminated with *S. aureus*;[18]
- bakery products contaminated during decoration or filling.[147]

47.7 FACTORS AFFECTING GROWTH AND SURVIVAL OF *S. AUREUS* AND PRODUCTION AND DESTRUCTION OF ENTEROTOXIN

47.7.1 Temperature

Growth. Most strains of *S. aureus* will grow aerobically at temperatures between 7° C and 48° C and have an optimum growth temperature of 35° C to 40° C. Generation times in foodstuffs stored aerobically at 35° C to 40° C can be as short as 20 min, with times increasing to 1 to 2 hours at 20° C, 5 to 10 hours at 15° C and 12 to 24 hours+ at 10° C.[82] Growth rates in vacuum- and gas-packed foods are usually significantly slower than in air-packed foods, the specific growth rates depending on the product composition, storage, and packaging conditions.[22,75,100] Lag times (times to the commencement of growth) are similarly affected by temperature and may vary from 1 to 7+ days at 10° C to 2 to 3 hours at 35° C to 40° C.[82] Lag times are particularly affected by the previous history of the cell; thus, lag times for cells damaged by harmful conditions such as freezing, drying, or heat will be variable, but much longer than the times mentioned above. After growth commences, the previous history of the cell does not affect the growth rate or the amount or rate of enterotoxin production.

Survival. *S. aureus* survives freezing well, and at –18° C will survive in meat and poultry for at least 6 months with little or no change in cell numbers;[164]

however, significant kill will occur at temperatures of –10° C and above in some substrates.[167]

Staphylococcus aureus has a heat sensitivity typical of most Gram-positive bacteria, ie, a *D* value of 1 to 6 minutes at 60° C (z = 6° C to 10° C) when heated in high a_w foods such as milk, meat, and vegetables;[11,56,60] $D_{60° C}$ values in phosphate buffer (pH 6.5 to 7.5) range from 1 to 2.5 minutes.[166] As would be expected, cells become much more resistant to heat when heated in a low a_w food. Thus, a $D_{60° C}$ value in milk of 5.3 minutes was increased to 42.3 minutes in milk containing 57% sucrose,[87] and a *D* value of 3 minutes in an egg pasta mix of a_w 0.92 was increased to a $D_{60° C}$ value of >40 minutes in an egg pasta mix adjusted to an a_w of 0.80.[78] Also the $D_{60° C}$ value in a meat product containing 3% to 4% NaCl was increased from 6 to 25 minutes to when the salt content was raised to 8.4%.[19] Lowering or raising the pH from neutrality reduces the heat resistance.[146] Cells of *S. aureus* heated in oil or fat can show remarkably high heat resistance (ie, a $D_{120° C}$ value of 3 to 6 minutes; z = 33° C);[65] however, the presence of small amounts of moisture significantly reduces this heat resistance.[170]

Other factors that will affect the measured heat resistance of *S. aureus* include: the temperature at which cells are grown, ie, cells grown below 30° C are much less resistant to heat than cells grown at 37° C, whereas those grown above 40° C are more resistant;[142] age of cells, ie, early log phase cells of *S. aureus* are about one-third as resistant to heat as stationary phase cells;[159] recovery conditions—the optimum temperature and pH for the recovery of heat-damaged cells of *S. aureus* are 32° C and pH 6.0.[5]

Heating causes damage to the cell systems that produce catalase and protect the staphylococcal cell from peroxides. The addition of blood or pyruvate to the recovery medium protects the cell while recovering from this heat-induced damage, allowing the recovery of most of the heat-damaged cells.[15,61]

Enterotoxin Production. Enterotoxins are produced under a narrower range of temperatures than those permitting growth, with temperature affecting both the amount and rate of production; the optimum temperature for enterotoxin production is the same as that for growth. There is extensive literature on the effect of temperature on enterotoxin production in foods;[82] however, because of the different numbers of organisms used as inocula, the effect of different microfloras (qualitative and quantitative) on growth and enterotoxin formation, and the very different sensitivity of methods used to detect whether enterotoxins have been formed, it is difficult to compare results obtained in one series of experiments with another. In one study, sufficient enterotoxin (SEA) to cause illness was produced in pasteurized milk with an initial microflora of 10^4 ml^{-1} stored for 6 hours at 35° C, 18 hours at 25° C, and 36 hours at 20° C, whereas in milk with an initial microflora of 10^6 ml^{-1}, these times were doubled, and in milk with an initial microflora of >10^6 ml^{-1}, SEA was detected only in the milk stored at 37° C.[54]

The limiting temperature for enterotoxin production is about 10° C. At this temperature, the rate of enterotoxin is very slow and in one experiment, 4 weeks were needed to produce detectable SEB from an inoculum of 10^6 g^{-1} in ham.[66] With a similar size of inoculum in brain heart infusion broth, using a more sensitive enterotoxin detection system, SEA was detected after 2 weeks at 10.5° C but not after 4 weeks at 9.3° C.[133] The maximum temperature for enterotoxin production is 45° C to 46° C, but this limit can be raised by several degrees by growth in the presence of 1M sodium chloride.[79] At suboptimal growth temperatures, the concentration of cells needed to produce sufficient enterotoxin to cause illness is increased, and a concentration of cells of approximately 10 million g^{-1} or ml^{-1} is required at temperatures of 20° C to 25° C.

Enterotoxin Destruction. Staphylococcal enterotoxins are resistant to freezing and destruction by heat. They will survive all types of commercial pasteurization processes and may even survive some used for the sterilization of canned foods.[23] In whole milk, enterotoxin survived heating for 20 minutes at 121° C ($D_{120° C}$ = *ca.* 20 minutes), and based on heat destruction, data at lower temperatures were estimated to have a z value of 29° C.[149] In a cream of vegetable soup (initial concentration 2.5 µg ml^{-1}), SEA survived a thermal process of f_0 = 3.0 minutes;[23] heat resistance is significantly reduced at acid pH values.[149] Heat may result in the loss of antigenicity of enterotoxins before loss of biological activity. Urea treatment of extracts from heat-treated foods, prior to use of immunological methods for enterotoxin testing, has been used as a means of restoring antigenicity.[23,24]

47.7.2 Water Activity

Growth and Survival. *Staphylococcus aureus* is one of the most tolerant foodborne illness-causing bacteria to low water activity and grows at a_ws well below those of other foodborne pathogenic bacteria.

Optimal survival is at a_ws of 0.07 to 0.16.[134] In dust, death rates increase at a nonuniform rate with increase in relative humidity (RH), reaching a maximum at an RH of 50% to 60%; survival rate under dry conditions decreases with increased temperature.[98] Death rate under dry conditions also is affected markedly by the availability of air, and Rahn concluded that the death rate of *S. aureus* is proportional to the square root of the oxygen concentration.[124] The adverse effect of air on the survival of *S. aureus* under dry conditions can be illustrated by experiments in which cells were inoculated into dry foods adjusted to different a_ws and stored in air and under vacuum at 25° C and numbers of survivors counted during storage. In a cake mix (a_w 0.53), the time for a 99.9% decrease in count was 8 weeks in the air-stored cake mix but 18 weeks in the vacuum-stored product; at a_ws of 0.00 to 0.22, there was virtually no change in the initial inoculum count during 27-week storage of the vacuum-stored cake mix, and only a 90% decrease in numbers in the air-stored mix.[42]

The limiting a_w for growth depends mainly on humectant, atmosphere, pH, and temperature. The limiting a_w for the growth of *S. aureus* in brain heart infusion broth (pH 7.0) incubated aerobically at 30° C was 0.86 in the presence of sodium chloride and 0.89 in the presence of glycerol;[101] the optimum a_w for growth in the presence of sodium chloride was 0.97 (4.0% NaCl).[80]

The interacting effects of temperature, atmosphere, and pH on the limiting a_w for the growth of *S. aureus* are illustrated in Table 47–4.

This table shows that the limiting a_w for growth is lower under aerobic than anaerobic conditions and that strains producing enterotoxins A, B, and C have similar growth limits; lowering temperature and pH gave expected increases in the limiting a_w for growth.

Enterotoxin Production. Table 47–4 also shows the effect of a_w on the production of SEA, SEB, and SEC; SEA was produced at much lower a_ws than SEB or SEC under all conditions of growth. The limiting a_w for the production of detectable enterotoxins (detection limit 50 ng ml^{-1}) was significantly higher than that limiting growth.

47.7.3 pH

Growth and Survival. The range of pH values at which *S. aureus* is able to grow is approximately 4.0 to 10.0 under otherwise optimal growth conditions; the optimum pH for growth is pH 6.0 to 7.0. At the extremes of pH, growth is very slow. Thus in UHT milk adjusted to acid pH values by the addition of HCl, the lag and generation times at pH 4.3 were respectively 2.8 days and 1 day at 10° C, 2.7 days and 14.4 h at 13° C, and 11 h and 2.6 h at 20° C.[82]

Organic acids at equivalent pH values to those obtained using inorganic acids are, as would be expected, more effective against *S. aureus*. Survival times in the presence of acetic acid depend on temperature; in mayonnaise at pH 3.9 (0.39% acetic acid), the survival time of an inoculum of 10^7 cells ml^{-1} was 1 day at 30° C and 9 days at 10° C;[163] 1% acetic acid at pH 5.0 also is bactericidal.[3] At equivalent concentrations of undissociated acid, lactic and citric acids are less effective than acetic acid against *S. aureus*; citric acid is used by the cell as a carbon source.

Enterotoxin Production. Staphylococcal enterotoxins are produced under a more limited range of pH values than those allowing growth, and the practical limit in acid foodstuffs is pH 5.0. The reported optimum pH values for the production of enterotoxins suggest that this lies between pH values 7.0 and 8.0. Staphylococcal enterotoxin A is produced under a wider range of pH values than is enterotoxin B.[130] For example, SEA was produced in mayonnaise adjusted to pH 5.1 and stored at 37° C, whereas SEB, SEC, and SED were produced only at higher pH values.[69]

47.7.4 Gases

Staphylococcus aureus grows faster under aerobic than anaerobic conditions and, as noted above, also produces enterotoxins under a wider range of temperatures and pH values when grown aerobically (Table 47–4). However, survival is better under anaerobic conditions. Thus in a series of experiments on the growth of *S. aureus* in nitrogen- and air-packed sandwiches stored at 26° C, growth rates were higher in the air-packed sandwiches, and enterotoxins were produced much faster in the latter; enterotoxins A and D also were detected much earlier than enterotoxin B.[22] Carbon dioxide (75%) was inhibitory to growth in sliced cooked beef at 12.8° C.[75]

47.7.5 Preservatives

Growth and Survival. *Staphylococcus aureus* is sensitive to sorbic acid, and in a model meat product with pH values 5.4 and 5.7, 5000 ppm was bactericidal.[143] In the same product, 1000 ppm of a mixture of 3:1 w/w sorbic acid:glycerol monolaurate was inhibitory in product with a pH value

Table 47–4 Limiting Water Activities for Growth and Enterotoxin* Production by Cocktails of Strains of S. *Aureus* Grown under Aerobic and Anaerobic Conditions in Brain Heart Infusion Broth at 37° C and 22° C[12]

of 5.4, and stored anaerobically at 35° C; 200 ppm sodium nitrite was inhibitory to anaerobic growth at pH 5.4 and aerobic growth at pH 5.7.[143] Nitrite is more inhibitory to growth under anaerobic than aerobic conditions.[92]

S. aureus will grow in the presence of >20% NaCl under optimal growth conditions, although in foods stored at temperatures <20° C, 15% will prevent growth. The inhibitory effect of NaCl is increased markedly in the presence of the antioxidant butylated hydroxyanisole (BHA). Thus, in the presence of 100 ppm BHA, 3% NaCl was inhibitory to growth in trypticase soy broth (pH 6.0) at 37° C and under the same conditions with 7% NaCl, 50 ppm BHA was inhibitory.[144] Ethanol at concentrations above 7% is inhibitory to *S. aureus* and 9% or more is bactericidal.[112,135]

Enterotoxin Production. With the exception of information on the effect of curing salts (see Section 47.7.2), there is little information on the effect of preservatives on enterotoxin production. The small amount of information available indicates that they have no specific effect on enterotoxin production other than what can be explained by their effect on growth. Thus, the limiting concentration of a preservative, such as sorbic acid, on enterotoxin production is close to the minimum inhibitors concentration (MIC) value for growth. However, in one series of experiments, ethyl-4-hydroxybenzoate had a pronounced effect on enterotoxin production and prevented production at concentrations that had no effect on growth.[82]

47.7.6 Irradiation

Staphylococcus aureus is sensitive to ionizing irradiation, and *D* values between 0.2 and 0.4 kGy have been reported in a variety of meat and fish products.[122,123,139] Staphylococcal enterotoxins are extremely resistant to ionizing irradiation and are unaffected by sterilizing doses.

In phosphate buffer (pH 6.8) a dose of 100 Kergs mm^{-2} of ultraviolet light (wavelength 250 to 280 nm) gave a 2 log kill of *S. aureus* at –79° C, whereas at 22° C a dose of 500 Kerg mm^{-2} was required for this kill; the difference was that at –79° C, there was no shoulder on the survival curve.[7]

47.7.7 Disinfectants

Staphylococcus aureus is sensitive to the wide range of disinfectants used by the food industry. Typical values at ambient temperatures (15° C to 30° C) for destruction in the absence of protein are: hypochlorite (10 ppm), 5 log kill in 30 seconds; quaternary ammonium compound (QAC) (30 ppm), 5 log in 30 seconds; Iodophor (10ppm), 5 log in 30 seconds; peracetic acid (200 ppm), 5 log kill in 1 minute; hydrogen peroxide (300 ppm), 5 log kill in 5 minutes; phenolic household disinfectant (10,000 ppm), 5 log kill in 10 minutes.[85,86,108] In the presence of protein, the amounts of these disinfectants to give equivalent kills will be significantly higher. For instance, in a dry milk film, 200 ppm of chlorine and a contact time of 2.5 minutes were found to be necessary for a 5 log kill[109] and the presence of even small amounts of protein, ie, 0.5% skim milk, resulted in more than doubling of the amounts of QAC, iodophor, and chlorine required to give a 5 log kill.[86]

47.7.8 Competitive Microorganisms

Staphylococcus aureus is a poor competitor and growth is readily prevented by other microorganisms. This is well illustrated by poor growth in raw meat but excellent growth in cooked meats. The reasons for such poor growth are variously described to be the result of: the production of organic acids, resulting in the lowering of pH; the utilization of oxygen by competitor microorganisms, resulting in the reduction in E_h and anaerobiosis; depletion of a specific nutrient; and the production of specific antimicrobial factors.[113] All or some of the factors may play a role in some foods, but the most likely causes of inhibition in foodstuffs are pH drop and anaerobiosis. The production of antimicrobial substances against *S. aureus* has been claimed for a wide range of bacteria including pseudomonads, enterobacteriaceae, bacillaceae, and fecal streptococci, these organisms affecting growth as well as enterotoxin production.[71,102,110] However, the production of specific antimicrobial substances was not demonstrated by these workers and, although a possible role of bacteriocins and other antimicrobial substances (such as hydrogen peroxide) cannot be ruled out, there is little evidence to support their role in inhibiting *S. aureus* in foodstuffs.

47.7.9 Interactions

In most foodstuffs, no single factor controls the growth, survival, or enterotoxin production by *S. aureus*, but rather a combination of factors such as reduced a_w, pH, E_h, and temperature.[141] Such interactions have been studied in most detail by those concerned with the mathematical modeling of microbial growth or survival, where the aim has been to develop models able to predict the fate of an organism in a foodstuff subjected to a particular process, formulated in a particular way, and/or stored under certain conditions.[148] One of the best illustrations of the effect of interacting factors on *S. aureus*, and its ability to produce enterotoxin in a foodstuff, is to consider the production of a traditional fermented, dry salami characterized by Genoa and Hungarian salamis. The principal factors preventing the growth of *S. aureus* in such salamis are shown in Exhibit 47–1; see also Chapter 19.

Exhibit 47–1 Factors Affecting Growth and Toxin Production of *Staphylococcus aureus* in Fermented Sausages[112]

Abiotic Factors

1. Physio-chemical factors: pH, E_h, and a_w.
2. Additives: type and amount of carbohydrate; nitrites/nitrates; glucono-D-lactone; NaCl; spices.
3. Conditions during sausage manufacture: Oxygen tension; temperature; humidity.

Biotic Factors

1. Number of *S. aureus* cells initially present in meat.
2. Use of starter culture: type and inoculum size.
3. Numbers and types of competitive organisms present.

Source: Adapted with permission from G.J.E. Nychas and J.S. Arkoudelos, Staphylococci: Their Role in Fermented Sausages, *Journal of Applied Bacteriology, Supplement*, Vol. 69, pp. 167S–188S, © 1990, Blackwell Science, Ltd.

These factors include selection of meats and other ingredients used in sausage manufacture that are free from or only contain low numbers of *S. aureus*; promoting a rapid drop of pH to <5.3 by use of a suitable starter culture, combined with an appropriate fermentation temperature; and drying under conditions of controlled humidity and temperature to promote thorough drying throughout the sausage to the predetermined water content. Measurements of the fate of *S. aureus* during the salami manufacturing process show the tendency for better growth of *S. aureus* at the surface of salamis fermented in the presence of air, with the production of enterotoxin only in the surface layers; the growth of *S. aureus* at the surface of sausages fermented in brine is inhibited, an effect claimed to be the result of the greater inhibitory effect of nitrite under anaerobic storage conditions.[92] The use of modified atmosphere packaging during the ripening of salamis has been suggested as a means of reducing the possibility of enterotoxin production.[92,141]

47.8 PRINCIPLES OF DETECTION AND ENUMERATION

47.8.1 Detection of *S. aureus*

Isolation. Many methods have been described for isolating *S. aureus* from foods and other sources. The productivity of these methods has been reviewed and assessed by many workers.[9,125,151] The solid (agar) media that may be used for the isolation and enumeration of *S. aureus* in foods can be divided into three broad types.

- The first, and most simple of these media, uses sodium chloride as the selective agent and incorporates a metabolizable substrate such as mannitol (production of acid), blood (hemolysis), or milk (zones of clearing/precipitation) as diagnostic agents.[16,81] These media have three main problems: they lack specificity (there are many salt-tolerant organisms other than *S. aureus* in foods); the substrates used to indicate the presence of *S. aureus* also are metabolized by other organisms; and cells of *S. aureus* when subjected to stress, by, for instance heating, drying, or freezing, become sensitive to NaCl and will not be recovered on salt-containing media unless they are first allowed to recover in a salt-free medium.[15,81]
- The second group of media contain a combination of substances intended to achieve good selectivity, with egg yolk as the diagnostic agent. *S. aureus* uses the lipoprotein lipovitellenin, contained in egg yolk,[136] resulting in the formation of clear zones around colonies of *S. aureus* growing on an egg-yolk–containing agar medium; this may be followed, on further incubation, by the formation of a white precipitate within the clear zones as a result of precipitation of calcium and magnesium salts of fatty acids released by the hydrolysis of fat.[153] The types of selective agents used in this group of media include antibiotics, such as polymyxin and sulphamezathine, and inorganic salts such as lithium chloride, potassium thiocyanate, and potassium tellurite. The latter compound is metabolized by *S. aureus* with the release of tellurium, resulting in the formation of black colonies, which is a further useful diagnostic feature on tellurite-containing media. Examples of this second group of media are tellurite polymyxin agar,[45] KRANEP agar,[138] and Baird-Parker agar.[16] The latter medium has been subjected to many international trials, demonstrating a generally superior performance over other media and thus remains the medium of choice for the enumeration of *S. aureus* in foodstuffs.[8,9,37,97,151] The good performance of this medium depends on: a balance of selective agents (lithium chloride, glycine, and potassium tellurite) to inhibit Gram-negative and Gram-positive bacteria other than *S. aureus*; the inclusion of sodium pyruvate to protect *S. aureus* cells damaged by heat from being killed by peroxides and other oxidizing agents (such damaged cells lose the ability to produce catalase); and the presence of egg yolk, which, in addition to providing one of the main diagnostic features of the medium, also assists in the recovery of damaged cells.

  There are a number of variants of Baird-Parker's medium intended for particular situations. The addition of sulphamezathine is recommended for the detection of *S. aureus* in raw meat and fish products, where overgrowth by *Proteus* spp. may occur,[140] and for generally heavily contaminated products, the further addition of acriflavine and polymyxin is recommended.[52] The prolonged storage of prepared plates of Baird-Parker agar may result in loss of selectivity, so if plates are intended to be stored for more than 48 h, it is recommended that the stable (pyruvate-free version of the medium) be used, the pyruvate being spread onto the medium immediately before use.[77] Good descriptions of the preparation and use of Baird-Parker agar will be found in the following references.[37,81,97]
- A third group of media has been devised to overcome one of the principal drawbacks to the use of egg-yolk–containing media for the detection of *S. aureus* in foodstuffs, namely that some strains from animal sources (principally from cattle), do not use lipovitellenin as a substrate and hence colonies do not show clearing on egg-yolk–containing agars.[14,91] This problem is well-recognized by those using the medium for the examination of dairy products, and they rely mostly on the typical morphology and color of colonies of *S. aureus* on Baird-Parker agar, as indicators of *S. aureus* presence. However, the need for additional testing to confirm *S. aureus* is a limitation to the use of this medium and this has led to the development of Baird-Parker medium containing pig plasma[83] or rabbit plasma with bovine fibrinogen[21] in place of egg yolk. The diagnostic feature is thus the coagulation of the plasma, resulting in a zone of precipitation around and beneath a positive colony. These methods continue to show promise, but because of cost and variable performance of commercially available plasmas, they are not used widely. The use of the egg-yolk–containing Baird-Parker medium continues to be the preferred method.

The use of solid media for the detection and enumeration of *S. aureus* in foods may be limited to the amount of food that can be spread on a plate. In practice, no more than 0.5 to 1.0 ml of a 10% suspension of a food can be spread on a standard agar plate without overloading the plate with particles of food, making the plates difficult to read; this amount can be increased to 1 to 2 ml on large size Petri dishes. With the normal dilution of a food (1 in 10), the limit of detection is 10 to 20 cells ml^{-1} or g^{-1} of food, unless multiple or large plates are used. This is adequate for most purposes, but if the detection of less than 10 cells is required, a most probable number (MPN) tube method should be used. For this purpose, the medium of Giolitti and Cantoni[68] with the addition of Tween 80[81] is recommended. Confirmation of the isolation of *S. aureus* is obtained by plating out positive (black) enrichments onto Baird-Parker agar or some other selective and diagnostic medium. More recently, the US Association of Official Analytical Chemists' approval was given to a more simple enrichment broth for MPN determination of *S. aureus*. This is based on the use of trypticase-soy broth containing sodium chloride as the selective agent with the addition of sodium pyruvate to aid the recovery of stressed cells.[96] The use of enrichment broths to isolate low numbers of *S. aureus* from foodstuffs is further discussed by Baird and Lee.[9]

Confirmation. The principal method used to confirm that an isolate is *S. aureus* is to apply the coagulase test. The preferred test format is the tube coagulase test using either human or rabbit blood plasma as the test substrate;[37,81] citrated plasmas should be avoided as the breakdown of citrate by some organisms growing on egg-yolk agars, eg, fecal streptococci, may result in false-positive reactions.[14] If the "slide coagulase test" is used (this will detect the presence of the clumping factor), the organism should be subcultured onto a nonselective medium before carrying out the test.

A variety of rapid and convenient tests for the detection of staphylocoagulases are available commercially; these are mainly based on the slide coagulase or clumping factor test. They include a latex agglutination test that detects the clumping factor and protein A, and plasma-coated red blood cells detecting the clumping factor.[4,39] It should be noted that the production of coagulases is not a property of only *S. aureus*, but other bacteria, including some Gram-negative bacteria and other staphylococci such as *S. hyicus* and *S. intermedius* will also coagulate plasmas. On tellurite-containing media, *S. intermedius* will not be confused as the organism produces gray colonies. *Staphylococcus hyicus* (principally found on pigs) may be confused with *S. aureus*, and for a definitive diagnosis it is advisable to use additional biochemical tests such as the API Staph-Ident system or the VITEK Gram-positive Identification Card; differentiation is also possible using a slide coagulase test as *S. hyicus* does not produce the clumping factor.

The production of Protein A[40] or TNase[35,93–95] by *S. aureus* is used by some workers as a diagnostic feature, although the use of these properties as confirmation tests would not appear to have any advantage over the coagulase test. However, the TNase test has a useful role in food microbiology because it will survive conditions, eg, pasteurization, that would destroy *S. aureus* but not the enterotoxins. Thus it can be used as a screening test for possible presence of enterotoxins; the microslide method is particularly useful for this purpose.[95]

Future methods for the detection of *S. aureus* in foods and other materials will probably include tests based on the detection of 16S and 23S rRNA sequences or mRNA using reverse transcriptase and DNA probes.[26] Nucleic acid-based probes can also be used as confirmation tests for *S. aureus*.[63,166]

47.8.2 Detection of Staphylococcal Enterotoxins

The traditional use of animal tests for the detection of staphylococcal enterotoxins has been replaced by sensitive immunological methods for their detection and identification.[28,29] The sensitivity, reliability, and convenience of these methods have continued to improve with the advancements made in antigen-detection systems.

The methods used in the 1960s were based on the classic Ouchterlony double-diffusion plate method with the microslide version of the technique being the preferred version of the test as it was more economical on reagents;[38] however, this method was relatively insensitive (limit of detection was ~ 0.5 $\mu g\ ml^{-1}$ of food extract). To be able to detect enterotoxins at concentrations able to potentially cause illness, ie, 0.01 $\mu g\ ml^{-1}$, lengthy extraction and concentration procedures taking 4 to 5 days to complete were required. The need for these extraction and concentration procedures was largely removed by the development of more sensitive antigen detection techniques. The first of these used radioimmunoassay procedures[44] and were not therefore suitable for wide-scale use by the food industry. The development of enzyme immunoassay (EIA) methods for enterotoxin detection and typing and in particular enzyme-linked immunosorbent assay (ELISA) methods[59,121] and the reverse-passive latex agglutination test[129] has led to the widespread availability of sensitive and convenient assay methods. These methods could only be used as suitable polyvalent and more recently monovalent antisera became available and this depended on the application of modern protein purification techniques by Bergdoll and others to purify the SEs and to use these to make high-quality antisera.[27,155] Methods of SE detection now are available commercially and have reduced preparation and detection time from several days to a few hours. The following is a description of the performance and use of four of the most widely used, currently available test kits.

- **Bommeli Kit** (Bommeli, Switzerland). This is an EIA kit based on the use of monovalent antibodies to SEA to E and was one of the first available commercial kits for SE detection. The specific antibodies are attached to plastic balls, which are used as the enterotoxin capture and detection system. The use of this method for foods requires extraction, taking 1 to 2 days to complete. The method has good sensitivity (0.1 to 10 ng ml^{-1} of food extract) but interference by food components has been reported leading to some false-positive and -negative results.[20]
- **TECRA Kit** (Bioenterprises Pty., Australia). This EIA kit uses polyclonal antibodies to SEA–E as capture antibodies in a standard microtitre format plate. It is widely used, having high sensitivity (1 ng ml^{-1}), speed (results in 4 h), and convenience. The method generally has good reliability but some false-positive results may arise from the presence of peroxides and non-enterotoxin metabolites in foods.[48,118,119,169]
- **VIDAS Kit** (Biomerieux, France). This is one of a series of test kits for use with the automated VIDAS ELISA system. It detects SE A–E, and is very fast (results in 80 min) and sensitive (1 ng ml^{-1}). Versatility and good performance (there are few reports of false-positive and -negative results) has led to wide use by laboratories involved in the frequent examination of foods for enterotoxins.
- **Oxoid Kit** (Oxoid, England). This is an RPLA (reverse-passive latex agglutination) test using monoclonal antibodies for SE capture and detects SE A–D. While it lacks the sensitivity, specificity, and speed of EIA/ELISA test kits, it is simple to use and does not require special equipment for carrying out the test. It does, however, require the use of a concentration step to be applied to a food extract before applying the test, and various food components interfere with the test leading to false-positive and -negative reactions.[117,129]

All methods used to test for SEs in foods appear potentially subject to interference by food components and microbial metabolites, although a recently described kit (RIDASCREEN™), based on the use of monoclonal antibodies to SEA-SEE as capture antibodies, was shown in a recent interlaboratory trial to be fast (results in 3 h), sensitive (1 to 2 ng SE g^{-1}), and highly specific.[120] Also heat and other agents capable of denaturing SEs may interfere with its immunological detection; the use of urea to renature enterotoxin subjected to such denaturation has been proposed.[24]

Despite continued improvement in the performance of commercially available kits for enterotoxin detection, it is strongly recommended that the definitive confirmation of SE in a food, or its absence, should be based on obtaining the same result using at least two different test procedures.

The use of oligonucleotide probes to detect the enterotoxin genes of *S. aureus* has been the subject of a number of recent studies, and probes to all the major SEs have been synthesized;[74] however, it has been questioned by some workers whether such probes are useful for the examination of foods for SEs. There are two potential problems associated with their use. The first is that the probe will only demonstrate the potential to produce SE and therefore can only be used as a screening test for possible presence of enterotoxin; for definitive demonstration of the production of an SE, a direct test for enterotoxin must be used. The second is that *S. aureus* strains that would seem not able to form SEs possess DNA sequences that are silent or mutant copies of the SE gene and probes, therefore, will give a false impression of the potential of a strain to produce enterotoxin.[116]

47.9 CONTROL
